This brings us to the law of comparative advantage, or, as von Mises calls it, the law of association. This law holds that *human cooperation in a division of labor is mutually advantageous even when one party is productively superior to the other in every way, because it allows the superior party to concentrate on those areas of his superiority which are greater and more important—i.e., on his areas of comparative advantage.* By the same token, the inferior party concentrates on those areas in which his inferiority is less or less important, which represents *his* comparative advantage.¹⁰⁶

Although originally advanced by Ricardo to show that international free trade and division of labor are mutually advantageous even if one country could produce every single good without exception with less labor than its trading partners, the principle of comparative advantage is all-pervasive, which is why von Mises calls it the law of association. It is found not only in the case of the boss and his secretary or the boss and the janitor, but also in such other everyday cases as the physician and his X-ray technician, the architect and his draftsman, the engineer and the mechanic, and so on. These are all cases in which one party could almost certainly do the work of the other

in less time than the other does it, but in which it does not pay him to do it, because it would mean time away from his own work, in which his superiority is greater. In the light of this principle, it is clear that even a productive genius as great as Edison can benefit from being able to employ the humblest cleaning lady, despite the fact that he could almost certainly clean his office in the barest fraction of the time it takes her to clean it. Employing the cleaning lady enables him to devote whatever time he would otherwise have to devote to cleaning, to inventing, where his productive superiority over the cleaning lady is incalculably greater than it is in cleaning, however great it is there.

In the case of international trade, a good example of the principle of comparative advantage would be the following. Assume that with modern technology and mechanized picking, the United States can grow coffee in hothouses with less total labor, including the labor of building and maintaining the hothouses, than is required to grow it in the open air in Brazil, where it must be picked by hand. Specifically, imagine that the labor required to produce x bags of coffee in the United States is 1 million man-days, while in Brazil it is 2 million man-days. Assume further, however, that in the United States it is possible to produce y automobiles with .5 million man-days of labor and that the same quantity of automobiles requires 5 million man-days of labor in order to be produced in Brazil. These assumptions are shown in Table 9–1.

Will the United States grow its own coffee and undersell Brazil even on coffee, merely because it can produce it with less labor than Brazil? The answer is no. It will pay the United States and Brazil each to concentrate on their areas of *comparative advantage* and to trade. The United States will not devote 1 million man-days to producing its own coffee. Instead, it will devote perhaps an additional .5 million man-days to producing automobiles—its area of comparative advantage—and exchange them for the quantity of coffee it would have cost 1 million man-days to produce at home. The effect will be that the United States gets its coffee and saves the labor of .5 million man-days, with which it produces additional products, to be enjoyed in addition to the coffee.

The Brazilians will gladly give x bags of coffee for y of automobiles, because in doing so, they obtain for 2 million man-days of labor devoted to growing coffee a quantity of automobiles that would have cost them 5 million man-days of labor to produce. Thus, division of labor and trade are still mutually advantageous. The absolute advantage of the United States in growing coffee is irrelevant, because it gains much more by concentrating on automobile production, in which its absolute advantage is far greater.

Table 9-1
The Absolute Advantage of the United States over Brazil

Labor Required In (country)/ to Produce (product)	United States	Brazil
<i>x</i> of Coffee	1 million man-days	2 million man-days
<i>y</i> of Cars	.5 million man-days	5 million man-days

It should be realized, incidentally, that to the degree that the United States does concentrate on cars, and Brazil on coffee, *the total combined production that both countries obtain from the same amount of labor increases*. If there is no concentration, and each country simply produces its own coffee and its own automobiles, then the United States produces x of coffee with the labor of 1 million man-days, and y of cars with the labor of .5 million man-days. Brazil produces a further x of coffee with the labor of 2 million man-days, and a further y of cars with the labor of 5 million man-days. The combined output of the two countries, obtained from the labor of 1.5 million man-days in the United States and 7 million man-days in Brazil, is $2x$ of coffee plus $2y$ of cars.

But now, if the United States gives up growing coffee and switches the labor previously employed in producing coffee to producing cars, it can produce $3y$ of cars. If Brazil gives up automobile production and switches the labor previously employed in producing cars to producing coffee, it can now produce $3\frac{1}{2}x$ of coffee. The total combined production of the two countries obtained from the same total labor thus increases from $2x + 2y$ to $3\frac{1}{2}x + 3y$ —just by virtue of employing the labor along the lines of comparative advantage.

Production increases because the United States gives up the production of a good in which its superiority is 2:1, in order to expand the production of a good in which its superiority is 10:1; at the same time, Brazil gives up the production of a good in which its inferiority is 1:10, in order to expand the production of a good in which its inferiority is 1:2.

Not only does the total of what is produced increase, but also each of the two countries necessarily gains by following the law of comparative advantage. The ability of both countries to gain rests not only on the fact that the total of what is produced is greater and thus that more is available to be had by both countries, but also on the following consideration: Namely, because the United

States can produce $2y$ of cars with the same labor as it requires to produce x bags of coffee, it will be willing, if necessary, to offer as many as something just short of $2y$ of automobiles for x bags of coffee. So long as it can obtain its coffee for less than $2y$ of automobiles, it obtains it for less labor than it would have had to expend in producing the coffee. At the same time, Brazil is prepared to accept for x bags of coffee anything more than $.4y$ of automobiles, since by devoting the labor required to produce x bags of coffee to producing automobiles, it could produce only $.4y$ of automobiles. (This follows from the fact that it takes Brazil 2 million man-days to produce x bags of coffee and 5 million man-days to produce y of automobiles. Two million man-days is $.4$ times 5 million man-days, and if the product of the 5 million man-days is y of automobiles, the product of 2 million man-days is $.4y$.) Hence, Brazil comes out ahead so long as it can obtain anything more than $.4y$ of automobiles for x bags of coffee. Thus, within the broad limits of anything less than $2y$ of automobiles for x bags of coffee and anything more than $.4y$ of automobiles for x bags of coffee, both the United States and Brazil are able to gain from the arrangement.

International Competition and Free Labor Markets

The introduction of money into the preceding example will help to reinforce the conclusion that it is economically worthwhile for each country to concentrate on its areas of comparative advantage, and will make possible wider applications of the principle.

Assume simply that wage rates in the United States are more than double what they are in Brazil—say, triple. In this case, even though it takes only half the labor to grow coffee in the United States as in Brazil, it will be *one-and-a-half times more expensive* to do so—because of our higher wage rates. Thus, on a dollars-and-cents basis, the United States would be led not to grow coffee. We would concentrate on producing automobiles, where

our cost would be three-tenths of Brazil's (after allowing for the effect of our three-times higher level of wage rates applied to our one-tenth the quantity of labor).

The question may be asked of how we know that our wages will be more than twice as high as Brazil's and thus that it will pay us to leave coffee growing to Brazil? We know because it follows logically that if American wages are not more than twice as high as Brazil's, economic forces will soon make them so. All we need do is assume that initially our wages are no higher than Brazil's, and then see what happens.

In other words, what we are assuming now is the nightmare case of the Brazilian protectionists. For in this case, with wage rates the same in the United States as in Brazil, it is cheaper to produce everything in the United States, and the United States could undersell Brazil even on coffee. But what will happen under these conditions? The answer, which the protectionists claim to know all too well, is that Americans won't buy anything from Brazil, while Brazilians will try to buy everything from the United States. That is exactly right.

But what is the consequence of this? The consequence is that money leaves Brazil and enters the United States. In Brazil, the effect will be less spending—less demand—for labor and goods. In the United States there will be somewhat more demand for labor and goods. (I say somewhat more, because being a much larger economy, the transfer of any given sum of money will represent a much smaller percentage increase here than it does a decrease there.)

If the freedom of competition exists in Brazil, wages and prices in Brazil will come down as the result of the drop in demand, while in the United States, they will rise somewhat. They will continue falling in Brazil and rising in the United States until the change in relative wages, costs, and prices between the two countries makes Brazil the cheaper country for the United States and other countries to buy from as often as the United States and other countries are cheaper for Brazil to buy from. Only then will money stop flowing out of Brazil and her wages, costs, and prices stop falling. Since our productivity-of-labor advantage in coffee is relatively modest, our cost advantage there will be among the first to disappear as Brazilian wage rates fall and ours rise.

It follows from this discussion that *there is room for every country in the world market*. However backward it may be in its methods of production, it can still be competitive in whatever it sells, provided only that its relative money wage rates compensate for its deficiencies in the productivity of labor.

To further bear this out, imagine, for example, that the labor of one country was uniformly half as productive as that of another—i.e., twice the labor was required to

produce every good. Such a country would nevertheless have the same costs of production and be able to sell profitably at the same prices as the more productive country, provided only that its wage rates were half as great. For half the wages per hour times double the number of hours equal the same costs of production. In the same way, if its productivity of labor were a third, a fifth, or a tenth as great, it would have the same costs of production and be able to sell profitably at the same prices as any more advanced country, provided only that its wages were a third, a fifth, or a tenth as great as those of its more productive competitor. The principle that emerges is that *every country can be internationally competitive provided that its relative level of money wage rates corresponds to its relative productivity of labor*.

The mutual gains that accompany every country's presence in the world market stem from the fact that the differences in the productivity of labor are not uniform: there is comparative advantage. A country with half the productivity of labor and thus half wage level almost certainly does not have half the productivity of labor in the production of each and every good, but just as a kind of weighted average. In the production of many goods, it has less than half the productivity of labor; in the production of many others, it has more than half the productivity of labor. In the cases in which it has less than half the productivity—i.e., requires more than twice the labor to produce a good—its wage level of one-half prices it out of the market and it imports; but in every case in which it has more than half the productivity—i.e., requires less than twice the labor to produce a good—its wage level of one-half puts its costs below those of its competitors and it exports. In this way, each country tends to curtail the production of some things and expand the production of others, and thus to participate in the international division of labor in accordance with the principle of comparative advantage. The very fact of each country's expansion of its areas of comparative advantage then makes possible still further economies associated with division of labor and production on a larger scale.

In each country that enters into free trade, prices fall relative to wages, which increases the buying power and standard of living of the average wage earner in that country. Where it is necessary for wage rates to fall in order for a country to become competitive, the prices of domestically produced goods and services tend to fall in the same proportion. Some of these goods and services are now cheaper than foreign-produced goods and services and so are exported. But some foreign-produced goods and services are still below domestically produced goods and services and so are imported. The ability to get these foreign-produced goods and services represents

a fall in prices greater than the fall in wages.

As illustration, consider again the case of the two countries one of which, on average, is half as productive as the other. If wage rates in the less productive country are initially 60 percent of the wage rates of the more productive country, they must fall by one-sixth in order to become only 50 percent as great. This fall in domestic wage rates reduces domestic costs of production and prices by one sixth. Thus, as far as domestically produced goods are concerned, the wage earners in the country have not lost any buying power, because prices are lower by as much as their wages. Where they gain is from the fact that now imported goods will be available to them which continue to be lower in price than domestically produced goods. These goods are the goods that require more than twice the labor to produce at home than abroad, and which thus continue to be more expensive to produce at home despite the fall in domestic wage rates to half the level of the foreign wage rates. At the same time, of course, the fall in domestic wage rates to half the foreign level gives the country concerned a cost advantage in all those cases in which its productivity of labor is anything more than half as great as the foreign country's—that is, in which it requires less than twice as much labor to produce a good. The proportion of its labor force which is no longer employed in producing the goods that are now imported will be employed in producing goods of this latter description instead, which are exported and which are the source of benefit to the wage earners of the foreign country.

The preceding examples bring to light a split vision on the part of protectionists. In the backward countries, the protectionists claim that free trade will be ruinous because of the higher productivity of the more advanced countries. In the more advanced countries, they claim that free trade will be ruinous because of the low wages of the backward countries—that to have free trade with the low-wage countries is to “import their standard of living.” The truth is, of course, that the higher productivity of labor of the more advanced countries tends to be counterbalanced by their higher wages, and the lower wages of the backward countries tends to be counterbalanced by their lower productivity of labor. This is what tends to occur on a weighted-average basis. In all the individual cases that deviate from the average, i.e., in which one or the other country retains a cost advantage, we have the mutual gains from comparative advantage.

The source of problems in international trade is the persistence of wage rates that are too high in relation to a country's productivity of labor. If a country has two or five times the average productivity of labor of its trading partners, then it can be competitive with wage rates two or five times as high as theirs, but not with wage rates,

say, two-and-a-half or six times as high as theirs. By the same token, the countries with the low productivities of labor can be competitive with wage rates of a half or a fifth, but not two-thirds or one-fourth those of their trading partners.

In a labor market subject to the freedom of competition, such undue differences in wage rates could not persist. The unemployment resulting from them would drive down wage rates and costs and restore the country's international competitiveness and the full employment of its workers as well. But where labor unions, minimum-wage laws, and other government interference prevent wage rates from falling, or from falling sufficiently, the problem of unemployment remains and tends to grow worse. More and more companies that have kept their prices competitive, and paid the higher wages at the expense first of funds for capital improvements, and then at the expense of dividends and funds for capital replacement, must finally cut back or go out of business altogether. This is exactly what has occurred in the United States in the automobile industry, the steel industry, and in many other branches of industry.

Government intervention in the form of confiscatory taxation, inflation, and deficit spending has deprived American business of the capital funds required for raising the productivity of labor. Labor legislation and the resulting union wage scales and union work rules, and all manner of government regulations have also operated to prevent the rise in the productivity of labor, or actually to reduce it. Meanwhile, foreign competitors, in countries with policies less hostile to capital accumulation and with less labor union and regulatory interference, have rapidly improved their productivity of labor. This combination of circumstances is what has made vast segments of American industry unable to compete at today's relative wage levels, which were inherited from an era of great relative superiority in America's productivity of labor. (All this, of course, is usually ignored. The most popular explanation of the problem is such trivialities as the alleged bad judgment of the American automobile companies in continuing to produce large cars after critics of the American standard of living had made known their preference for small cars. References to alleged cycles of inevitable decline are another popular explanation.)

The actual solution to the United States' lack of competitiveness (and to all of our other politico-economic problems, as well) would be to abolish all the government interference and establish laissez-faire capitalism. That would end the destruction of the American economic system and allow it to rebuild and resume the rise in the productivity of labor. But this almost certainly will not be done. What most likely will be done is that foreign

competition will be severely restricted. The effect of that will not only be that the American people will lose many of the benefits of international division of labor. It will also contribute to future wars.

Countries like Japan, with huge populations and small territories, vitally depend on being able to export manufactured goods in order to be able to import food and raw materials. If we close them out of major export markets, we threaten their vital interests. We give them grounds for enmity and an economic rationale for war, as a means either of forcing open markets or of seizing the food- and mineral-producing territories they are prevented from earning the foreign exchange to buy from, and making them into captive markets.

Of course, for now and for the foreseeable future, the Japanese are not capable of being a military threat to us. Interestingly, however, as if to remedy this, the same U.S. Congress which has tried to restrict Japanese exports to this country has also urged Japan to increase her military expenditures.

A major implication of this whole discussion is that one of the requirements of free international trade, and thus of world peace, is free labor markets within countries. That is what is necessary to keep a country's wage level in a proper relationship to the wage levels of its competitors, and so enable it to have free trade without fear of mass unemployment developing because it is too widely undersold. A further implication is that since labor legislation and the coercive labor unions it spawns are incompatible with the establishment of the necessary relative wage levels, they are incompatible with free trade and thus, in the long run, with friendly international relations and world peace. It should be obvious that this consideration alone demands the abolition of such legislation.

Comparative Advantage Versus the Infant-Industries Argument

Recognition of the gains from comparative advantage can serve as the basis for a refutation of the so-called infant-industries argument. The infant-industries argument is the claim that new industries require tariff protection until such time as they have become established and are in a position to stand on their own. Thus, according to this argument, the means for developing new industries is to concentrate on industries in which one is currently relatively inefficient and would not pursue on the basis of following the law of comparative advantage. Then, by means of the employment of coercion in one's favor—namely, protective tariffs—one will somehow be able to grow more efficient and later on be able to operate in the industry under conditions of free competition.

The economic error of the infant-industries argument is that it fails to see that the quickest way to become efficient in new industries is to acquire the capital necessary to become efficient in them. The quickest way to do that is to concentrate on those areas in which one can earn the highest income and thus be in a position to save and invest to the greatest possible extent, which means: to follow the law of comparative advantage. As illustration, imagine that I as an individual want to go into business for myself, but at present, because of my lack of capital, the only way I can do so is at the level of buying a frankfurter pushcart, which will enable me barely to earn a living. If I am in a position to earn a substantially higher income by virtue of working for someone else, and thus to save and invest much more heavily, it should be obvious that the most effective way to establish myself in business is to work for someone else until such time as I have accumulated the capital necessary to go into business for myself on an efficient basis, with a reasonable prospect of earning a higher income than I can by working for someone else—i.e., that I wait until such time as my comparative advantage in the face of my greater capital, leads me to go into business for myself.

Exactly the same common-sense principle applies to the conduct of a whole country. Thus, the fact that in the early years of the United States, comparative advantage meant that the United States should concentrate on agriculture, while Great Britain concentrated on manufacturing, implied that concentration on agriculture was actually the fastest route to efficient industrialization in the United States. The higher incomes earned by concentration on agriculture provided the ability to save and invest far more heavily than would have been possible on the basis of premature industrialization brought about by coercion. Concentration on agriculture was the foundation for the development of industry on an efficient basis, and thus for the far greater development of industry. To the extent that the United States, or any other country, has employed the coercion of tariffs and other government intervention to promote the development of unprofitable industries, its policy has actually served to retard the industrial development of the country, because it has served to make its people earn lower incomes than they could have earned and thus to be less capable of saving and accumulating the capital necessary for the development of industry.

Any gains that may have resulted to particular industries as the result of this policy were at the expense of greater losses to other industries, whose development was thereby prevented. The truth of this proposition can be clearly seen if we imagine that the government were to encourage my purchase of the previously mentioned

frankfurter stand, by means of giving me some kind of monopoly privilege in connection with the sale of frankfurters. Anything I might gain in this way would be at the expense of an equivalent loss to my customers. At the same time, I would be producing less than I could have been producing had I worked in another line. In addition, there would be less production on the part of whoever might have been in the business of selling frankfurters and who is now forced to find some less remunerative line of work because of my monopoly privilege. In exactly the same way, diverting part of the capital and labor of the whole country from efficient employment in agriculture to inefficient employment in industry, represents an equivalent economic loss. To whatever extent the reduced production is disguised by the coercive transfer of wealth, the loss of the victims is as great as the gain of the recipients. What remains is the reduction in production and thus in the ability to save and invest, and thus in the ability to develop industry.

Consideration of the law of comparative advantage provides the answer to those who complain about the alleged dangers to a country of being "overspecialized" and about its alleged need to diversify its economy to avoid such "overspecialization." The fact is that the gains from efficient specialization far outweigh any possible losses arising from lack of "diversity." This is obvious in the case of any individual. Thus, for example, a man works regularly as a house painter or truck driver. He does this rather than attempt to alternate between several employments, because he earns more income this way. Such specialization represents his comparative advantage. He gains even though occasionally the circumstances of the market cause the demand for his specialty to fall sharply. Despite such periods, he is far better off concentrating on his specialization. Any possible loss of income he might be spared in such periods by "diversifying" and dividing his time between more two or more regular employments, are far outweighed by the reduction in income he would have to experience in the much lengthier periods of normal demand for his specialty.

A government policy of forced diversification for the purpose of avoiding periods of slack international demand in the areas of its citizens' specializations, is comparable to forcing an individual who judges it best for him to be a house painter or truck driver, or whichever, to divide his time between two or more employments to avoid the occasional loss of income in his area of specialization. It represents forcing people to do that which they judge on net balance to be overwhelmingly against their interest, and which in fact is against their interest. This is the result even though the government does not force a given individual to pursue two or more lines of

work at the same time, but instead, for the sake of its citizenry collectively diversifying, uses such coercive means as protective tariffs and subsidies to force various portions of its citizenry to pursue full-time lines of work or branches of industry that are less remunerative to them as individuals than the lines of work or branches of industry they would have chosen on their own.

How the Less Able Can Outcompete the More Able in a Free Labor Market

The principle that wage differences compensate for productivity differences applies within the labor market of each country, as well as internationally. It shows how less efficient individuals can be fully competitive with more efficient individuals in seeking employment. All they have to do is accept wage rates that are lower to the degree that their productivity is lower. For example, a man who can lay only twenty bricks per hour can be fully competitive with workers who can lay forty bricks per hour, provided only that he be willing to accept half the hourly pay they receive. For then the cost to an employer per brick laid is the same.

Indeed, less productive individuals can, and regularly do, *outcompete* more productive individuals for jobs simply by virtue of their wages being lower to a greater degree than their productivity is lower. All other things being equal, the worker who can lay twenty bricks per hour and asks five dollars an hour outcompetes the worker who can lay forty bricks an hour but asks fifteen dollars an hour. The first man's cost per brick laid to an employer is only twenty-five cents ($\$5/20$), while that of the second man is thirty-seven-and-a-half cents ($\$15/40$).

The law of comparative advantage guarantees a job for everyone—a job in which he outcompetes all other contenders for that job, no matter how modest his abilities—provided only that the labor market is free to bring about the appropriate adjustments in relative wages.

As the wage rates of less capable people fall relative to those of people who are more capable, the less capable are able to match or exceed in more and more employments what a more capable person is able to offer an employer per dollar of cost. When the wages of a less capable person are half those of a more capable person, he is the more economical employee in every job in which his productivity is more than half as great as that of the more capable person. When his wages are only a third of the wages of a more capable person, he is the more economical employee in every job in which his productivity is merely more than a third as great as that of the more capable person, and so on.

By the same token, the relatively higher wage rates of those who are more capable operate to reserve their talents and abilities for those specific employments in

which their relative productivity is great enough to offset their higher wage rates. Our man with the three-times higher wage, for example, is the more economical employee in any occupation in which his relative productivity is more than three times as great as that of the less capable person. He is, of course, also the more economical employee in any occupation that the less capable person is simply incapable of performing at all and which at the same time is in sufficient demand to pay him the high wage he receives. The higher wage rates of more capable people, derivable from those employments whose requirements they alone can satisfy, or in which their relative productivity is otherwise sufficiently high, operate to keep such people *out of the portions of the labor market served by the less capable people*.

For example, an engineer or doctor capable of laying even a hundred bricks an hour would not dream of working as a bricklayer, nor could anyone dream of employing him as one, given his ability to earn, say, fifty or a hundred dollars an hour as an engineer or doctor. His relative productivity advantage as a bricklayer may be as great as five to one (that is, a hundred bricks an hour to twenty bricks an hour), but his advantage as a doctor or engineer gives him an income so high that, given the availability of workers who can lay twenty bricks an hour for only five dollars, he would need to have an unattainable relative productivity advantage of ten or twenty to one before such an occupation as bricklaying could afford him an income comparable to what he earns as an engineer or doctor. (This is putting aside the fact that he would almost certainly want a good deal more income as a bricklayer, to compensate for the greater unpleasantness and much lower social standing of the job.)

It is no exaggeration to say that at the appropriate level of relative wage rates, people with abilities no greater than those of a janitor are able to outcompete everyone else in the entire economic system—even the world's most talented people. They not only are capable of doing so, they actually *do so*—for such jobs as janitor: by being willing to accept the income of a janitor.

Thus, on the basis of the law of comparative advantage, there is room even for the least talented individuals in the productive system of a division-of-labor society. Even they have a contribution to make, and one that is of benefit to others who are more talented. Namely, by taking over tasks in which their productive inferiority is relatively small, they enable those who are more talented to concentrate on areas where their productive superiority is greater and more important.

Competition for jobs is not the enemy of such people. They can compete successfully for jobs appropriate to their abilities, provided they are free to accept the necessary wage rates. Indeed, free competition is precisely

what they need in order to be successful in getting the jobs they want.

The enemy of such people is the misguided attempt to give them wages they are unable to earn. That attempt—principally in the form of minimum-wage laws and pro-union legislation—is tantamount to *prohibiting* such people from competing. It prohibits them from competing by the one means that can compensate for their low productivity, namely, sufficiently low wage rates.

In the name of a misguided humanitarianism, people are stopped from competing, and the results are blamed on *competition!* The poor and weak, we are told, have no jobs and no income, because they have been overrun by the competition of the strong that casts them adrift and leaves them to perish. The actual fact, of course, is that the poor and the weak have not been harmed by the competition of the more able, but by *the police*, who are sent in by the “humanitarians” to enforce the laws to stop them from competing where they could successfully have competed.

The “humanitarians”—today's so-called liberals—are responsible for millions of low-skilled people, most notably, black teenagers, being prohibited from competing. Despite the “humanitarians'” alleged concern for human welfare, their ignorance of economics has led them to enact government policies that condemn millions to unemployment and a lifetime of poverty on the welfare rolls. Had these people been free to take a low-paying job, on the other hand, most of them would have gained some skills and experience that would have fitted them for better paying jobs later on. Many of them would have seen the need for further education and have gotten it.

Furthermore, it should be realized that the policy of attempting to enforce wage rates above the market level operates to *reduce* wage rates elsewhere. The higher wage rates imposed reduce the volume of jobs offered. The result is that workers who could have worked in such jobs cannot find employment in them and thus must seek work elsewhere. Thus, the supply of workers in other lines is increased, and wages elsewhere are put under pressure to fall. Because of this, every time labor unions succeed in artificially increasing the wages of skilled workers, they increase the supply of labor seeking employment in less-skilled jobs, and thus operate to reduce wages in the less-skilled areas artificially. It follows that in an economic system free of all government interference with wage rates, the wages of the unskilled would not have to be as low to establish full employment for them as is presently the case. The least capable members of the economic system not only could be employed under free competition, but could be so on more favorable terms than is the case under restrictions on the freedom of competition.

5. The Pyramid-of-Ability Principle

The law of comparative advantage explains the nature of the productive contribution of the less able to the more able. Now we must consider the incalculably greater productive contribution of the more able to the less able. In effect, having considered the contribution of the cleaning lady to Edison, let us consider the contribution of Edison to the cleaning lady. The principle we are now about to consider is *the pyramid-of-ability principle*, which is the name given to it by Ayn Rand, who was the first to identify it explicitly.¹⁰⁷

The principle can be stated as follows: *To the degree that those who are more able occupy the higher positions in a division-of-labor society, the productivity of those in the lower positions is increased.*

For example, if a better-qualified person becomes foreman in a factory, the workers under him will produce more than if a poorer-qualified person became foreman. If a better-qualified person becomes company vice president or president, all those working under him will produce more than if a poorer-qualified person got the position. If two people both want to be an automotive engineer, and the better qualified succeeds, while the less qualified ends up as an auto mechanic, the better-qualified one can raise the productivity of the poorer-qualified one by designing a better car for him to work on. If their positions were reversed, this would not be possible.

More broadly and fundamentally, if there is the freedom to invent new and better products and new and better methods of production, and to start and expand new lines of business that produce or implement them, the productivity of all who help to produce the goods or services concerned, or who use them in production, or who are simply enabled to buy them by virtue of the work they presently do, is raised. It is raised by the activities of the inventors, businessmen, and investors who made those improvements possible.

The division of labor itself, as it exists within every factory and workplace, is a marvelous example of how the activities of those who are more capable raise the productivity of those who are less capable. As explained in Chapter 4, their work of breaking the production of a product into a series of small, simple, repetitious steps, which they then concentrate and coordinate, allows people of very little ability to produce highly complex products, such as automobiles and television sets. The contribution of the more able to the productivity of the less able can be gauged by the fact that in a division-of-labor society even janitors, merely by the effort of pushing a broom, can actually obtain automobiles, television sets, and almost all the other products of modern technology—prod-

ucts which on their own they could never even imagine.

It follows from this discussion that in “losing” the competition for the higher positions in a division-of-labor society, those who are less qualified do not in fact lose, but win. Their productivity of labor and standard of living are raised by the greater success of those who are more able than they. Were they to somehow force their way into the higher positions, they would lose. For they would destroy the productivity of labor of all those who would be under them and thus the possibility of obtaining the goods they wanted.

For example, I would like to have the income of the president of General Motors, which is a substantial multiple of my own. If by some means, despite my total lack of knowledge and experience or even interest in the automobile industry, I could force my way into his job, I would certainly reduce the production of General Motors by an enormously greater amount than corresponds to any additional income I would receive. For I would be disrupting the work of hundreds of thousands of people and causing the misuse of billions of dollars of capital. Perhaps, if this were the only instance of its kind in the whole economic system, I might still have a substantial gain for myself—provided I didn’t have to trust my own life to GM products; the enormous loss I caused would fall almost entirely on others. But now suppose someone else similarly unqualified has become president of the airline I fly; or he’s the surgeon who will operate on me; and so on. As this sort of action becomes more widespread, it becomes impossible for anyone to gain from it. Everyone suffers losses—those who succeed in getting the positions they don’t deserve and can’t obtain under the freedom of competition, along with all whom they victimize. In this way, they would actually end up losing by virtue of trying to obtain the gains they don’t deserve.

Freedom of Competition and the General Gain from the Existence of Others

The pyramid-of-ability principle and the law of comparative advantage can be integrated into a wider principle that subsumes them both. Namely, that *each person gains from the existence of other people who participate with him in the division of labor*. If they are less productively capable than he, his gain from them is described by the law of comparative advantage. If they are more productively capable than he, his gain from them is described by the pyramid-of-ability principle.

In either case, looking down the scale or up, the individual gains from the existence of others who participate with him in the division of labor. *The great precondition of his gain is the freedom of competition: that everyone should have the legal right to enter every occupation and every industry.* That is the condition

which simultaneously guarantees him the widest possible scope for his own talents as a producer and operates to assure that everything he buys will be produced by those who are best suited to produce it, in an environment of constant progress and improvement. The freedom of competition is the true basis of his economic security and the diametric opposite of the law of the jungle. It gives a place in the system of division of labor to everyone, and tends to put everyone in the particular place for which he is best suited, with the result that the productivity and standard of living of all are increased and go on increasing. So far from being the law of the jungle, the freedom of economic competition emerges as the true principle of the universal brotherhood of man.

6. The Population Question

With the notable exceptions of Adam Smith and Frederic Bastiat, the classical economists taught, in sympathy with Malthus, that population growth represents a threat to the average standard of living. As explained in connection with the discussion of private ownership of land and “land rent” earlier in this chapter, their belief was that the larger the number of people, the larger the amount and poorer the quality of land and mineral deposits that must be worked to support them, and, at the same time, the more intensive the exploitation of each piece of land and mineral deposit worked, resulting in diminishing returns. For both reasons, they held, increases in population and in the number of workers tend to be accompanied by less than proportionate increases in the supply of food and minerals.

The clear implication of this doctrine is that there is an inherent conflict of interests among people as their numbers increase. It is tantamount to the claim that man is in the position of the lions in the jungle after all. The lions are at the point of a scarcity of food supply; man allegedly approaches it with every increase in his numbers. Indeed, Malthus was the inspiration for Darwin, whose writings were in turn the inspiration for the doctrine of conflict of interests presented under the name Social Darwinism.¹⁰⁸ A garbled form of Malthusianism is a root of the ecology movement’s hostility to population growth.

The fact is, however, that the classical economists’ ideas on the effects of population growth are valid *only for a stagnant, non-division-of-labor society*. (This was essentially the kind of society to which all but the most recent experience of the human race referred at the time that Ricardo wrote, which was in the early nineteenth century. He wrote too soon to know that he lived at the beginning of a radically new era in human history. Thus, it is understandable that neither he nor his followers were

able decisively to break with this pessimistic view.) In such a society, everyone lives in the same way—namely, as a self-sufficient farmer. In such a society, the existence of more people does mean the need for more and more land of progressively inferior quality and an ever worsening problem of diminishing returns. In such a society, it does mean the need to start farms higher and higher up the sides of hills or mountains, to extend farming to rockier patches of soil, or down into marshlands, and to subdivide existing farms among more and more people—all with the result of declining yields per unit of labor expended.

But this is not at all what the existence of more people means in a division-of-labor society. *In a division-of-labor society, a larger population means a greater, more intensive division of labor.*

Adam Smith alluded to this fact when he wrote that “the division of labor is limited by the extent of the market.”¹⁰⁹ The meaning of this proposition is that the extent to which the division of labor can be carried in the production of anything depends on the volume in which it is to be produced. If, for example, automobiles are to be turned out at a rate of, say, 10 or 20 a day in a given location, then it is impossible that a step which takes 5 minutes to perform on any one car could be anyone’s full-time job. The daily volume of automobile production would have to be increased to approximately 100 in a given location before such an operation could be made into a full-time job. (One hundred times 5 minutes equals 8.33 hours, which represents a full-time job.) The daily volume of automobile production would have to be increased to approximately 1 thousand in a given location, before an operation requiring only 30 seconds could be made into a full-time job, and so on. (One thousand times 30 seconds also equals 8.33 hours.) Thus, the larger the volume to be produced—the larger the market to be served—the further can the division of labor be carried.¹¹⁰

Markets, however, are not made possible by non-producing consumers, as Adam Smith well knew, but only by producers.¹¹¹ And without a larger total number of producers participating in the division of labor overall, a more intensive division of labor in the production of any one good would require drawing labor away from the production of other goods, and thus correspondingly reducing the extent of division of labor elsewhere. The only way to have a greater division of labor overall is by virtue of a larger population of participating producers. This alone permits the division of labor to be extended in some areas without being correspondingly reduced in other areas. Thus, when we refer to the connection between the division of labor and population, or the division of labor and markets, it must be kept in mind that

what is always referred to is a larger population of *producers*, and of overall markets that are larger by virtue of the existence of more producers.

Keeping this in mind, let us consider some further illustrations of the connection between the division of labor and the size of the population. Consider, for example, why large cities have so many specialized shops and restaurants, which are rarely found elsewhere. The reason is that the large population of such a city constitutes so vast a market that the statistically most infrequent tastes and interests are present in a great enough absolute quantity to make their accommodation possible.

For example, on any given evening perhaps only one person in ten thousand would like to eat Indian food. If the whole surrounding territory has only fifty thousand inhabitants, such a restaurant almost certainly could not survive, for it would have only five customers on an average evening. Its survival in such conditions would require patrons willing to pay very high prices. Only then could it be worthwhile for anyone to operate such an establishment. But in a large city or metropolitan area, with a surrounding population of ten million, say, there will be a thousand people, on average, wanting such food every evening. As a result, several such restaurants can exist and prosper.

The same principle applies to specialized book stores, equipment stores, and so on. It also explains why it is in large cities that one finds such cultural institutions as museums, opera companies, symphony orchestras, and so on, which appeal to refined and, in terms of their frequency of occurrence, relatively uncommon tastes. Only large cities have a sufficiently large market to provide a sufficient level of attendance for such institutions.

The advantages of a large population can be observed by considering the size of the population necessary for the existence of an economical-sized medical school, say, and for the existence of medical specializations. The principles observed in these cases will apply throughout the economic system.

Thus, as a hypothetical illustration, let us assume that an efficient-sized medical school produces 100 new doctors per year. This number, let us assume, is a number that represents enough students to keep the cost of lectures and demonstrations within reason on a per student basis, and yet not so many students that they cannot obtain sufficient individual consultations and so forth with the faculty. Let us assume further that the average graduate of this medical school will practice medicine for 40 years after graduation. This means that ultimately there will be 4,000 graduates of this school in practice at any one time. Finally, let us assume that the average frequency of diseases and accidents, and so on, that

require medical attention is such that in order to keep the average doctor more or less fully occupied, there have to be 1,000 people for every doctor. These assumptions imply that a population of *4 million* is necessary to provide a market large enough to support one efficient-sized medical school.

But this is by no means the end. For suppose that only one doctor in a thousand is a brain specialist. With a total of only 4,000 thousand doctors, there would be just 4 brain specialists. That is hardly enough to support much specialized research in brain diseases, a specialized journal of brain diseases, graduate programs or seminars in brain diseases, and so forth. A population of *4,000* brain specialists, however, would make these things possible. But that implies an underlying population not of 4 million, but of 4 billion people.

This same kind of radical step-up in the size of the population necessary to make further specialization possible occurs throughout production. Consider again the case of automobile production, where it was pointed out that for a full-time job to be made out of one specific step that requires 30 seconds per car, volume would have to be approximately 1,000 cars per day in a given location. Only this time, let us assume that the worker doing this job could be helped by a machine specifically designed for that purpose. If the total market for automobiles is limited to 1,000 per day, then there is room for only one such machine. Obviously, it would be impossible to have any regular employment in producing such machines. But suppose the market for automobiles is not 1,000 thousand per day, but 50,000 thousand per day, so that 50 such machines are required. Now it may be possible to have some people regularly employed just in the production of these machines, who will produce them with greater experience and expertise. Of course, their division of labor could not go very far: only a very few such machines would need to be produced in any one year. If there is a specific operation in building such a machine which takes a whole month, say, it is doubtful that even that operation could be anyone's full-time job, because it occurs so infrequently. A vastly larger market would be required to carry the division of labor to the point where even very large-sized steps in the production of these machines could be made into full-time jobs. It is doubtful if markets could ever be achieved that were so large that all possibilities for carrying the division of labor further in the production of specialized machines and tools would be exhausted.

Now it is necessary to realize how important are the gains a larger market provides not only in allowing the existence of further specializations and subspecializations, but also simply in allowing existing specializations and subspecializations to be carried on, *on a larger*

absolute scale. Our medical school example can illustrate this point very well.

Some kind of very small market, say a few hundred people, is necessary to allow one person to specialize as some sort of primitive doctor. A larger market of several million, that permits the existence of several thousand doctors, also permits them all to be trained in a medical school and creates the subspecialization of brain specialist. A still larger market increases the absolute number of brain specialists. And here we can easily see something that is vitally important. Namely, if the market is big enough to support 400, or better still, 4,000 brain specialists, rather than just 4, the likelihood of some important discovery being made about brain diseases is substantially increased. For there will be 400 or 4,000 highly intelligent and experienced people thinking about the problems involved, instead of just 4. And whatever any one of them discovers, can, of course, be quickly communicated to all the rest—through the journals, seminars, and so on that their number is large enough to support.

Again, exactly the same principle applies throughout production. The larger the size of the market, the greater is not only the number of the scientific and engineering specializations and subspecializations, but also the absolute size of all of them—and, equally important, the larger the absolute number of intelligent, innovative individuals prepared to go into the various lines of business. Thus, throughout the economic system, the chances of new discoveries and inventions being made, being quickly communicated throughout the fields concerned, and then being implemented are greatly increased. And thus the rate of economic progress accelerates.

The potential gains of this kind from a larger-sized population in a division-of-labor society can be thought of in terms of a doubled population having a doubled number of Edisons and Fords and the like. Indeed, in a division-of-labor society, a doubled population even with just one-tenth more of such innovators would probably be easily capable of overcoming any problems of diminishing returns and poorer-quality land and mineral deposits, and of doing so by an ever widening margin. It would do so through the greater technological progress that the existence of a larger number of such outstanding individuals would make possible. For the existence of each additional productive genius serves to raise the productive power of the whole human race. Because essentially what he supplies is *ideas*. Ideas can be used by everyone who has need of them without in any way diminishing their ability to serve others. They are an inexhaustible gift.¹¹²

What we have here in the existence of a larger population in a division-of-labor society is a further step-up in productive power along the lines of the multiplication

of knowledge used in production and the raising of the level of such knowledge to a standard set by the most intelligent.¹¹³ For now we have *a larger absolute number of the most intelligent*, which is bound to mean a more rapidly rising standard of knowledge used in production.¹¹⁴

Thus, the effect of population growth in a division-of-labor society is radically different than in a non-division-of-labor society. In a division-of-labor society it means a greater, more intensive division of labor, including the larger absolute size of the various specializations and subspecializations concerned with making new discoveries and implementing them in the form of new products and better methods of production—in a word, it means a greater absolute number of productive geniuses, whose work operates to raise the standard of living of everyone. These advantages enable a division-of-labor society easily to overcome any problems that would otherwise be associated with the need to produce more food and minerals for a larger population.

Worldwide Free Trade

The fact that a larger market provides important gains, in the form of a more intensive division of labor and a larger absolute size of the various specializations and subspecializations, implies the desirability of worldwide free trade. Under worldwide free trade, every producer would be able to regard the entire world as his market. Production could be carried on in each locality on the vastly greater scale commensurate with a world market. Thus, the division of labor could reach its maximum possible extent consistent with the existing size of the world's population and the proportion of it already incorporated into the division of labor within the various national boundaries.

One may believe that already, even with substantial trade barriers, the scientific and engineering professions of all the various countries are essentially integrated, and that knowledge flows freely among them, with the exception, of course, of the Communist and other totalitarian countries. This is probably true. But what cannot flow freely, so long as there are trade barriers, is the *implementation* of scientific and technological progress—in the form of improvements in products and methods of production. If we want that, we need access to all the business talent to be found in the world, which means: we need to establish the right of every businessman everywhere to sell his goods everywhere. So long as that is missing, the benefit of the existence of much business talent is largely lost, because it is kept out by tariffs and other trade barriers. In other words, people are deprived of the benefit of the existence of talented foreign businessmen. And, of course, they are deprived of the benefit

of all the economies of larger-scale production that free trade would make possible.

Free Trade and the Economic Superiority of the United States over Western Europe

The gains from free trade and the consequent access to a larger market can be illustrated by comparing the economic history of the United States with that of Western Europe. The fact that since the enactment of the Constitution there has always been free trade among the various states of the Union made the United States into a much larger free-trade area than Western Europe, in terms of population as well as land area. Because of its substantially greater population than any single West-European country, American businessmen were able to produce on a larger scale, with greater division of labor and more efficiency, than their West-European counterparts. A businessman anywhere in the United States could regard the whole territory and population of the United States as his market, and businesses were able to be built up accordingly. In Europe, on the other hand, tariffs and other trade barriers increasingly tended to restrict the markets of businessmen to the much smaller territories and populations of their respective countries.

By the same token, the American people had free access to the greater absolute volume of business talent to be found among its own greater population, while the people of most European countries were increasingly confined to the smaller absolute volume of business talent to be found among their smaller populations. These facts help to explain the more rapid rate of economic progress that prevailed in the United States than in Western Europe until fairly recently.

The fact that in recent decades West-European countries have greatly reduced their tariffs and other trade barriers against one another, under the aegis of the Common Market, has contributed to their rapid rate of economic progress in this period. Now, to a substantial degree, businessmen in any one member country can regard the populations of all the rest as part of his market. The combined population of these countries, counting that of the newer members, exceeds the population of the United States. The result has been an intensification of the division of labor within Western Europe and a much greater ability of the citizens of each member country to gain access to the talents of businessmen in the other member countries.

International Free Trade and Domestic Laissez Faire

The advantages of the United States from internal free trade and the gains from freer trade within Western Europe would be dwarfed by those derived from fully free trade on a world basis. But free foreign trade ulti-

mately requires a policy of laissez faire domestically. We have seen how in preventing necessary adjustments in relative wage rates government interference in the labor market causes free trade to result in mass unemployment, which leads to the abandonment of free trade. Similarly, government subsidy programs are incompatible with free trade: a government cannot, for example, try to raise the price of wheat in its country above the world-market level and at the same time allow the free importation of foreign wheat.

Some economists have held that external free trade is compatible with government intervention domestically, if governments abandon much of their political sovereignty to a supernational authority, which would impose a uniform policy of intervention. For example, the problem of wheat subsidies could be solved, it is held, if all countries in the trading area had the same subsidy program. To some degree, the European Common Market represents a relinquishing of national sovereignty to the organs of the Common Market. The ultimate success of the Common Market is widely thought to rest on the prospects for the political unification of Western Europe.

However, no uniform policy of government intervention can deal with such matters as the major differences between the productivity of labor in different areas. A uniform minimum wage between the United States and Taiwan, for example, would mean the virtually total destruction of the Taiwanese economy if it were set at the present American level, or, for all practical purposes, the total absence of a minimum wage in the United States if it were set at a level that would not destroy the Taiwanese economy.

Furthermore, the long-run effect of government intervention is to break up the unity of *existing* political entities, not to promote the formation of still larger political entities. For the existence of government intervention is an invitation to pressure-group warfare. Groups form to use the government as an instrument serving their short-run interests at the expense of the interests of the rest of society. In such an environment, such groups often come to be formed on the basis of such factors as regional ties, ethnic origin, and common language. Each such special group feels the need to control the use of government power in order to promote its own interests at the expense of other groups, and to protect itself from the depredations of other groups. In such conditions, growing conflict and hostility develop among the various groups, culminating in violent clashes and, ultimately, in demands for political separation. Thus, at the very same time that some people are calling for a United States of Europe, others are demanding the breakup of the existing countries of Europe. In Great Britain, there are the Scottish and Welsh nationalists; in Spain, the Basque and

Catalan separatists; in Belgium, the Flemish separatists; and in other countries, similar such groups.

Thus, international free trade and the gains to be derived from the international division of labor ultimately require the existence of domestic free trade—of laissez-faire capitalism. This is necessary to avoid both the surrender of national sovereignty and the pursuit of policies promoting the development of ethnic conflicts that lead to the rupturing of nations. With domestic laissez faire, there are no obstacles of any significant kind to the establishment of international free trade. There is no unemployment problem caused by free trade, because wage rates are free to adjust as necessary; no problem of protecting the recipients of subsidies, because there are none; and no problems of uniform government regulation, because there is no government regulation.

The Birth Rate

It has been shown that in a division-of-labor society a larger-sized population, far from reducing the average standard of living, actually increases it. This demonstration by no means implies, however, that the ideal arrangement would be the highest possible birth rate, or that birth-control measures operate to hold down the standard of living. There is an important difference between a larger-sized existing population, made up of self-supporting adults, and a rapidly growing population, composed of a high proportion of dependent children. The latter represents a reduction in the standard of living of those who must support the children.

Too-rapid population growth caused by a too-high birth rate is almost impossible, however, in a society which is not dominated by religious fanaticism and in which parents are financially responsible for the costs of raising their own children, and are free to practice birth control. For then, the parents simply consider the costs they will have to bear, and act accordingly. The only way a problem of population growth can be created in these circumstances is insofar as the government taxes the general public to pay for the costs of raising children. Then, people can have children at little or no cost to themselves; the cost is borne by the taxpayers. Welfare allowances geared to family size, so-called family assistance allowances, and public education are examples of measures of this type.

7. Free Immigration

It is necessary to address the issue of free immigration, which is closely related to the subject of population growth. This section will show that free immigration is in the long-run material self-interest of the citizens of a capitalist country.

The words *capitalist country* must be stressed. To the extent that a country has a welfare system, tax-supported hospitals and schools, public housing, and so on, and the immigrants come to take advantage of these offerings, the effect is a corresponding loss to the present inhabitants of the country, who have to pay the costs. The above proposition applies to a country insofar as it is *without* these and other welfare-state-type programs—a country in which the immigrants must be self-supporting and themselves pay for whatever they receive. By the same token, the freedom of a country implies the absence of economic disabilities imposed on immigrants: there are no minimum-wage laws or prounion legislation to prevent them from gaining employment, and no legal obstacles to their starting businesses, buying land, and so on.

Under such conditions, the freedom of immigration must ultimately prove economically beneficial to everyone. Because among the immigrants and their descendants will be individuals of great talent, capable of achieving great things in a free country, but who would be stifled and be able to contribute little or nothing in the lands of their origin. In effect, the freedom of immigration into a free country from countries that are less free or unfree is a vital means of *unlocking human talent and increasing the gains from the pyramid of ability*.

As a simple example, one should consider what would have been the effect on Andrew Carnegie, and not just on the American but on the world steel industry, if he had been prevented from immigrating to the United States and confined to the less free environment of Scotland and Great Britain. One should consider what would have been the effect on the development of the helicopter if Sikorsky had been prevented from immigrating to the United States from Russia. Is it likely that the Russians would have seen the value of his ideas before they had been proved by actual repeated demonstration in the United States?

Indeed, we should consider the effects if the *ancestors* of any American industrial innovator had had to remain in their native lands, and thus that person have been born and spent his life in a country like Italy, Poland, Russia, or Germany, or even France or Great Britain, instead of the United States. Probably most of the innovators would have been stifled or at least significantly held back.

The historical advantage noted in the previous section, of the people of the United States having access to more business talent than the people of any European country, was due to America's policy of greater economic freedom in general combined with her policy of free immigration in particular. The latter gave the United States a larger population from which to draw such talent, while the former ensured that in the larger population *a greater frequency of such talent would be manifested*,

because freedom is the essential condition for the development and flowering of such talent. The combination of free immigration and general economic freedom thus results both in more people *and*, at the same time, as an inextricable part of the same process, *a rate of economic progress that is not only rapid, but also further accelerated by virtue of the immigration*. Simply put, free immigration into a free country accelerates economic progress, *because talent requires freedom in order to flourish. Free immigration into a free country brings talent to freedom, and so enables more of it to develop and contribute to economic progress*. The acceleration of economic progress it achieves ultimately far outstrips whatever short-run problems may accompany an increase in immigration.

Refutation of the Arguments Against Free Immigration

It is necessary to refute the arguments advanced against the freedom of immigration and the population growth it causes.

It is claimed that the larger population resulting from free immigration creates the need to resort to inferior grades of land and mineral deposits and is accompanied by diminishing returns. This argument has already been answered both in our discussions of population growth and in our discussion of private ownership of land.¹¹⁵ Here it is only necessary to add a further point which applies particularly when the population growth results from immigration. Namely, that the immigration can be accompanied by the importation of additional raw materials along with the additional people.

Imagine, for example, that workers of the British steel industry immigrated to the United States and became steel workers here. This would not mean that the iron ore they required must be taken from the Mesabi range in Minnesota. Very probably, it would simply mean that iron ore that used to go from Labrador to Britain will now go from Labrador to the United States.

This example points up the fact that those who fear population growth are thinking in terms of a non-division-of-labor society, in which people work the land and in which more people in a territory means more working of the land in that territory. Actually, immigration into towns and cities has no necessary connection with the extent to which the land and mineral deposits of the surrounding territory must be worked, because the towns and cities can draw their raw materials from anywhere in the world. The notion that more people in a country must mean a higher ratio of labor to land in that country, and thus diminishing returns, simply does not apply in a division-of-labor society.

It is also claimed that a larger population must reduce

the productivity of labor because it means a higher ratio of labor to capital goods, or, what is the same thing, less capital goods per worker. Those who advance this argument believe that population growth and increases in the supply of capital goods are independent processes. Capital accumulation, they believe, is determined simply by saving, which allegedly has no connection with the growth of population.

The fact is that a larger number of people working and producing *is itself the cause of a larger supply of capital goods*. A larger number of people working and producing in conjunction even with an unchanged supply of capital goods results in an increase in total production. This no one can deny. It is only necessary to realize that what is produced in an economy is not only consumers' goods, but also *capital goods*. Labor and existing capital goods are used to produce both consumers' goods *and* capital goods, and, as we shall see in later chapters, they do so in accordance with the relative demands for the two types of goods.¹¹⁶

The implication of this is that if there is any single, one-time increase in the number of people working and producing, it automatically tends to be followed by a growth in the supply of capital goods per worker and thus in output per worker at least back to their original levels. This is because the larger number of workers produces more capital goods with which that same larger number of workers then works in the next period, and with the aid of which it enjoys a higher productivity. The further effect is another increase in production in the following period—both of consumers' goods *and* of capital goods, until the original levels of capital goods per worker and the productivity of labor are equalled and, indeed, surpassed.

Thus, it should be clear that no reasonable case exists against any single dose of immigration or population increase based on the argument that it reduces the amount of capital goods per worker. For the additional labor itself results in progressively more capital goods.

In the case of a continuous increase in the supply of labor, it could be argued that just as the first group of additional workers brings about an increase in the supply of capital goods, a second group arrives on the scene, so that the ratio of capital goods to labor does not increase and may even fall further. Yet even this, more sophisticated version of the reduced-capital-per-worker argument against immigration and population growth cannot stand. This is because if the productivity of labor were threatened by a relative excess of labor and a relative deficiency of capital goods, the effect would be a drop in the demand for labor, and thus in the wage earners' demand for consumers' goods, and a rise in the demand for capital goods. The effect of this, in turn, would be a

higher relative production of capital goods and a lower relative production of consumers' goods. The larger number of workers of each year would find sufficient additional capital goods available because they would be produced by a *larger proportion of the labor and capital goods of each year*, as well as by a growing volume of labor and capital goods from year to year.

And, as time went on, the positive effects of the unlocking of more human talent would occur. The effect of this would be an increase in the output of capital goods (and consumers' goods) that can be obtained from any given quantity of labor working in conjunction with any given quantity of capital goods. Even if it occurred on a strictly delimited, once-and-for-all basis, the effect of this in turn would be a more rapid rate of increase in the production both of capital goods and consumers' goods, with each year's larger output of capital goods serving as the base for the following year's further increase in the production both of capital goods and of consumers' goods.¹¹⁷

Thus, a capitalist economy with the freedom of immigration turns out in the long run to have a more rapid rate of capital accumulation than one without it. For it has both a larger relative production of capital goods and uses capital goods more efficiently in the further production of capital goods than one without the freedom of immigration. The effect of this more rapid rate of capital accumulation is a correspondingly faster rate of economic progress, which soon makes up for the reduction in the proportion of output going to the consumption of wage earners.

If one wants to form a more precise, quantitative estimate of the relationships involved, let us assume that free immigration, together with any increase in population coming from those already present, results in an overall rate of population growth of 3 percent per year. This is a rate last seen in the United States in colonial times. It would be sufficient to double the population every twenty-five years.

In order for a 3 percent larger number of workers each year to be as well equipped as the workers would be without population increase, something on the order perhaps of an additional 9 to 12 percent of national income—more accurately, current net output—would need to be devoted to saving and capital accumulation. This figure is generous. I arrive at it on the basis of the fact that in the nineteenth century and the first few decades of the twentieth century, the period in which the American economy was relatively free, the long-term historical ratio of reproducible capital to national income was about three or four to one.¹¹⁸ Thus, a 3 percent increase in capital to accompany the 3 percent increase in the number of workers and so maintain a three or four to one ratio of capital to output per worker, would repre-

sent no more than something on the order of 9 to 12 percent of national income in conditions in which the degree of capital intensiveness was substantially higher than it is today.

Having to obtain this 9 to 12 percent of national income from the share of national income previously going to wage earners, would represent something on the order of a one-time reduction in wages of about 13 to 17 percent, if, as is typical, wages initially constitute about 70 percent of national income. This magnitude of reduction in wages, however, greatly overstates the magnitude that would actually follow the establishment of free immigration. This is because it is predicated on going from *zero* population increase to an annual rate of 3 percent increase. In reality, the effect would be more likely to be to go from a 1½ percent annual increase without freedom of immigration to perhaps a 3 percent annual increase with it. The additional capital required would thus actually equal only 4½ to 6 percent of national income, rather than 9 to 12 percent; and the one-time wage reduction would be on the order of 6½ to 8½ percent rather than 13 to 17 percent.

If the freedom of immigration were introduced following the establishment of greater economic freedom in other respects, this short-run negative effect would probably go largely unperceived, since it would be more than offset by other, positive developments. But, in any case, if the effect of the freedom of immigration and the pool of talent it unlocks is to enable the productivity of labor to increase by just an additional 1 percent a year, then, as soon as this happens, within seven to nine years the initial loss is made good and thereafter the process results only in gains.

A third argument raised against the freedom of immigration is that its effect would be to reduce the wages of unskilled workers relative to those of skilled workers. This result would occur to the extent that such factors as their lack of knowledge of the language, and the possibly lower educational standards of the poorer countries from which they came, led the immigrants to enter the economic system more heavily at the unskilled end of the labor market than at the skilled end.

Now this argument would have weight only if it could be shown that the influx of unskilled workers substantially increased the short-run reduction in the standard of living of the present unskilled workers, over and above the reduction just discussed. This cannot be shown, because by the time the influx of immigrants is able to have a significant depressing effect on the relative wages of unskilled workers, it also exerts a significant positive effect on the absolute standard of living of everyone.

Consider. If the freedom of immigration means an

additional increase in the number of workers of about $1\frac{1}{2}$ percent a year, then whatever the proportions of skilled and unskilled labor among the immigrants, in any one year it can change the proportion among workers as a whole only very slightly. As a hypothetical illustration, if initially half the workers are skilled and half are unskilled, while among the immigrants only one-third are skilled and two-thirds are unskilled, the effect in one year is to change the overall composition of the labor force to a little more than $49\frac{3}{4}$ percent skilled, and a little less than $50\frac{1}{4}$ percent unskilled. (This conclusion follows by applying a rate of increase of 2 percent to the unskilled half of the population and a rate of increase of 1 percent to the skilled half of the population, and then expressing the results as percentages of the combined total.¹¹⁹)

Furthermore, this change in the relative composition of the labor force does not go on indefinitely, because as time passes more and more of the earlier immigrants move up the ladder into skilled jobs. And among their children, the proportion of skilled and unskilled workers will be about the same as among the original population.

But what is most important is that with each passing year in which the proportion of unskilled workers becomes more pronounced, until it finally levels off at its new equilibrium, more and more of the earlier immigrants have had time to achieve positions from which they can begin making contributions that raise the general standard of living. Thus, after ten years, say, while the overall proportion of unskilled labor has risen in our hypothetical example from 50 percent to about $52\frac{1}{2}$ percent, there will be immigrants who have established their own businesses and introduced important innovations having a growing impact on the rest of the economic system and operating to raise the standard of living of everyone. And with each passing year, this effect will become more pronounced. (The figure of $52\frac{1}{2}$ percent results from applying to the half of the population that is initially unskilled a compound rate of increase of 2 percent for ten years, and to the half of the population that is initially skilled a compound rate of increase of 1 percent for ten years, and then taking the former result as a percentage of the combined result.)

Thus, the effect of the change in the proportions of skilled and unskilled labor operates perhaps to postpone somewhat the restoration and increase in the standard of living of the unskilled workers. At the same time, it accelerates the restoration and increase in the standard of living of the skilled workers. For what happens is that while the unskilled workers, with their relatively lower wages, are unable to buy as many of the goods and services of the skilled workers, the skilled workers are able to buy correspondingly more of the goods and

services of the unskilled workers.

Thus, overall, the effect of free immigration is that the immigrants enjoy a substantial gain immediately, while the original population gains after a period of time, which is shorter for skilled workers and longer for unskilled workers. Within the span of a single generation it is likely that almost everybody will have gained and from that point on will gain more and more. For by then, the immigrants and their children will have been making important contributions for some time, and will continue to do so, while further changes in the proportion between skilled and unskilled labor will probably have come to a halt.

The fourth and final objection to the freedom of immigration is a noneconomic argument to the effect that it means turning the country over to foreigners and thus destroying its language and culture.

The fact is that for a capitalist country the *opposite* is true. The freedom of immigration is the principal means of extending the language and culture of such a country. For the immigrants come voluntarily, in order to take advantage of freedom and to benefit themselves. They come with the knowledge that they are now in a better country than the one they left behind, and so are well-disposed to learning its language and absorbing its culture. And because they come from many different lands, each with its own language, the language of the new country is the logical common ground for them to choose in dealing with one another. Learning it is also virtually indispensable for practical success, since almost all of the existing wealth of the country is in the hands either of its native inhabitants or of earlier immigrants who have learned the language to be able to deal with the native inhabitants. It was in just this way that English came to be the language of tens of millions of people who originally did not speak English; people who, along with learning English, made the most important parts of Anglo-Saxon culture their own, such as the idea of the rule of law and the sanctity of private property.

The immigrants, of course, do not merely absorb their new country's culture. They help to make it better. They contribute to it not only all their business, scientific, and artistic achievements, and what is valuable in their own heritage, but, perhaps most important of all, a constantly renewed sense of personal ambition and personal achievement. They are a fresh inspiration in every generation.

The fact that while two hundred years ago English was the native language of perhaps 12 million people out of a world population of 1 billion, and is today the native language of over 350 million people out of a world population of about 4 billion, is due principally to the existence of the freedom of immigration into the United

States. The ability of the United States to become the leading economic and military power in the world would not have been possible without its freedom of immigration, which both attracted the numbers and powerfully contributed to their per capita productivity. Had the United States adhered to its policy of free immigration—along with the rest of its freedom—it is probable that today it would have a population approximately twice as large and a standard of living at least twice as high as the population and standard of living it presently has. As such, it would so far surpass any combination of external powers as to be absolutely unassailable.

Free Immigration and International Wage Rates

The discussion of free immigration that has just been presented implies the necessity of modifying an important proposition of economics—namely, the proposition that the movement of workers from lower-paying to higher-paying jobs brings about an equalization of wage rates. This proposition must be limited to a context in which the jobs are performed *under the same degree of economic freedom and cultural rationality*. The movement of workers from lower-paying jobs in less free, less rational countries to higher-paying jobs in a freer, more rational country does not equalize wage rates, but increases the differences still further, because the productivity of labor in the freer, more rational country will tend to grow all the more rapidly relative to the productivity of labor in the other countries, thanks to the unlocking of human talent and the capital formation that is brought about in the freer, more rational country. Thus, free immigration contributes to the emergence of virtually two different worlds, as population moves from politically created wastelands into countries in which freedom and rationality make possible continuous economic progress.

It should now be clear that the freedom of immigration into a capitalist country is to the long-run economic self-interest of all of its inhabitants. It enables more talent to flourish and thus increases the rate of economic progress in that country, through the greater operation of the pyramid-of-ability principle.

Capital Export

Closely related to the subject of freedom of immigration is the subject of capital export. Just as the immigration of labor is feared, on the grounds that it will reduce the ratio of capital to labor in the country experiencing the immigration, so the export of capital to foreign countries is also feared, on exactly the same grounds. The ratio of capital to labor, and thus the productivity of labor and real wages, will allegedly be reduced either by the im-

migration of labor or by the exportation of capital. Thus, for example, at the time of writing, objection is widely voiced to the prospective export of capital from the United States to Mexico, as the result of the impending establishment of greater freedom in the economic relations between the two countries. (It is rather ironic that most of those who fear the export of capital from the United States also fear the import of capital into the United States—from Japan, for example. It seems that the enemies of economic freedom have two fears in connection with the movement of capital: its movement out of a country and its movement into a country.)

The answer to the fears concerning the export of capital is essentially the same as the answer to the fears concerning the immigration of labor. Namely, that it too is the source of more rapid capital accumulation, including, ultimately, more rapid capital accumulation in the countries that export capital. Capital is exported only because it can be employed more productively abroad than at home. That is why it is more profitable to export the capital than to keep it at home. But the fact that capital can be employed more productively abroad than at home—that the same capital has a larger product abroad than at home—implies that the production of capital goods, no less than the production of consumers' goods, will be larger than before. For capital goods no less than consumers' goods are the product of capital goods and labor. Anything which serves to increase production in general serves to increase the production of capital goods.¹²⁰ Thus, the freedom of the Japanese to export capital to the United States, and the freedom of the United States to export capital to Mexico, makes possible the production of more goods—more capital goods as well as consumers' goods—with the same total labor and capital goods than would otherwise be possible. Thus such freedom increases the overall rate of capital accumulation.

Insofar as capital is exported to develop the exploitation of foreign natural resources and to take advantage of special climate and growing conditions found abroad, its beneficial effect on the capital-exporting country is obvious. For now raw materials and other products become available to the domestic market of the capital-exporting country that would not otherwise be available or available as economically. The effect is an immediate rise in the standard of living of the capital-exporting country. The effect is also a rise in the standard of living of all other countries that obtain the benefit of the expanded and improved production of minerals and agricultural commodities, through their import of such commodities.

The export of capital for the purpose of developing foreign manufacturing is similarly advantageous. Once again, an expanded and improved supply of products becomes available wherever these products are sold. If

the major market for these products is the capital-exporting country, then its citizens have the most benefit from the larger supply of products.

As far as the expanded production that results from the export of capital—whether to develop foreign natural resources, foreign agriculture, or foreign manufacturing—is an expanded production of capital goods, the effect is, as I say, a further increase in the ability to produce, everywhere that the additional capital goods become available. For now these capital goods are added to the supply of capital goods otherwise existing and thereby raise the productivity of labor. The result of this higher productivity of labor is a greater ability to produce, including a greater ability to produce capital goods. Thus still more capital goods become available, followed by a still greater ability to produce, followed by an even greater supply of capital goods, and so on. This process is capable of continuing indefinitely, causing the supply of capital goods, the ability to produce, and the standard of living to go on rising further and further, and thus to be higher everywhere throughout the world than they would otherwise have been.¹²¹

An essential foundation of the permanently higher rate of capital accumulation attendant on the freedom of capital export is the intensification of the international division of labor that freedom of capital export brings about. Freedom of capital export is the means of bringing previously undeveloped or backward territories into the international division of labor and thereby enabling any given quantity of labor and capital goods to produce more, including, of course, more capital goods, by virtue of the intensification of the division of labor that is achieved.

Economic history, precisely the economic history of the United States and Mexico, provides a clear demonstration of the consequences of capital export. A major portion of the present-day United States—Texas and the whole of the Southwest and California—once was a part of Mexico. The economic development of this vast area was made possible by substantial capital export from the Eastern United States. However, although its original foundation was capital exported from the Eastern United States, most of the capital that is today invested in this region did not actually come from the Eastern United States. Rather it was accumulated out of the increasing production of the region itself (or out of goods obtained in exchange for that increasing production). Thus, the capital exported from the Eastern United States provided the foundation of the capital accumulation of the former Mexican territories but not the substance of it. A major by-product of the increasing production of the region, of course, was a growing supply of products in the Eastern United States, which, as far as they were capital goods,

made an important contribution to all aspects of economic progress in the Eastern United States. In other words, the fact that Texas and California and the other states that once were part of Mexico have developed as they have, has greatly contributed to capital accumulation, production, and the standard of living in the rest of the United States. Had the United States of the nineteenth century attempted to retain all of its capital east of the state of Texas, in order to avoid the allegedly harmful consequences of exporting capital to “Mexican territory,” the effect would have been a United States that in succeeding decades was far poorer than it turned out to be.

Today, there may be the opportunity to export capital to the remaining territory of Mexico. To the extent that the United States is free, the process of the economic development of the remainder of Mexico could only be accompanied by further improvement in the economy of the United States. The development of this remaining part of Mexico, if it can actually take place, would have the same impact on the economy of the United States as the development of Texas and California.

It should be evident that in the nature of the case there is no inherent reason for the export of capital to be accompanied by unemployment. Many people, of course, must change their jobs as the result of such a process, but in a free economy the overall effect is no reduction of employment, but merely a rise in the productivity of labor and standard of living.¹²²

8. The Harmony of Interests in the Face of Competition for Limited Money Revenues

Going beyond the various aspects of international economic competition, the case for the freedom of economic competition in general becomes stronger still when one considers its benevolent effects in the context which might be thought most hostile to it, namely, the context of a fixed, invariable quantity of money and volume of spending in the economic system. In such a context, each person’s gain of sales revenues and money income would imply a corresponding loss of sales revenues and money income by someone else. I will show that in such a context the effect of economic competition is necessarily to reduce prices by an amount sufficient to compensate, indeed, more than compensate, for the loss of money revenue or income in the rest of the economic system. This demonstration will constitute a further validation of the principle that in a division-of-labor, capitalist society, one man’s gain is not another man’s loss, but other men’s gain.

Thus, for the sake of further reinforcing the case for freedom of competition by confirming it even in these

rather extreme circumstances, let us imagine an economic system in which gold is money and all the gold has been mined, so that no further increase in the quantity of money is possible.¹²³ If the quantity of money were to become fixed in this way, then, as Chapter 12 will show, there would be no basis for a rising volume of spending in the economic system, nor, therefore, for a rising volume of sales revenues and money incomes earned. This is because the increase in all of these depends on the increase in the quantity of money.¹²⁴

For the sake of convenience, let us assume that the fixed quantity of money generates a volume of total spending and therefore of total sales revenues in the economic system equal to 1,000 units of money per year, year in and year out. Let us further assume, for the sake of simplicity, that the 1,000 of sales revenues earned each year constitute 1,000 of net incomes to the sellers. If one likes, each of the 1,000 units of money spent and received can be conceived of as equal to \$5 billion or more of our present money, so that the economic system we are imagining could be physically as large as our own is now.

Let us also assume that this hypothetical economic system is initially composed of two groups of producers which are equal both in the number of their members and in the productive ability of their members. Thus, initially, each of these two groups produces half of the total output of the economic system. Because equal outputs command equal prices and exchange for equal revenues, we are justified in inferring that the sales revenues and incomes of the two groups are initially equal at 500 units of money each.

Now, to show the benevolent effects of competition, let us imagine that over a period of years, while both groups remain the same in terms of the number of their members, the members of one of the groups succeed on average in doubling the productivity of their labor, while the members of the other group merely maintain the productivity of their labor. The effect of this will be that one of the groups doubles its production while the production of the other group remains unchanged. This, in turn, means that one of the groups will now account for two-thirds of the output of the economic system while the other group now accounts for only one-third of the output of the economic system.

On the principle that equal outputs command equal prices and sell for equal revenues, we can infer that the members of the group that has doubled its production will now earn two-thirds of the total sales revenue and income of the economic system while the members of the other group will now earn only one-third of the total sales revenue and income of the economic system. Because total sales revenue and income are fixed at 1,000, the consequence is that the revenue and income of the

group that has doubled its output increases from 500 to 667, while the revenue and income of the group whose output remains unchanged decreases from 500 to 333. These changes are in accordance with the changed relative contributions of the two groups to the total product of the economic system in the face of a fixed 1,000-monetary-unit value of that product.

Thus, the picture may appear to be one of a conflict of interest between the members of the two groups. The totality of sales revenue and income is strictly limited and the members of the one group gain sales revenue and income only by equivalently depriving the members of the other group of sales revenue and income.

Here one must keep in mind the fact that the nature of the competition is not a grabbing off of a limited supply of something from nature by means of the exercise of greater physical strength and agility, but the earning from willing consumers of a greater share of money revenue and income by means of the enlargement of the supply of goods produced in exchange for that revenue and income. A number of benevolent consequences follow from this fact that are crucial, and they can be seen at their clearest precisely in the present case.

The first such consequence is that totally unlike the conditions in the animal kingdom, where the success of the strong deprives the weak of means of subsistence, the success of the more productive never deprives the less productive of the ability to earn at least some revenue and income. In the present case, the relatively less productive group still earns a full one-third of the sales revenue and income of the economic system, corresponding to its one-third contribution to total production. It would not matter by how much it fell behind in its relative contribution to total production, it would still earn revenue and income in proportion to whatever it did produce.

For example, if the members of the more productive group increased their productivity ninefold instead of twofold, the consequence would be that their relative production would rise from 1:1 to 9:1, instead of to only 2:1. Under these conditions, the members of the group that did not increase its productivity, instead of accounting for a third of the output of the economic system and earning a third of the revenue and income of the economic system, would account for only a tenth of the output of the economic system and earn only a tenth of its revenue and income. In other words, its members would earn 100 of revenue and income. This 100 is still something, and so long as the members of this group produce anything at all, they will still account for some positive proportion of the output of the economic system and earn a corresponding proportion of the revenue and income of the economic system.

And here is where we find the second benevolent consequence of the nature of economic competition that is brought out in the present analysis—a consequence that may appear astonishing. This is the fact that precisely to the same extent that the money income of the group that does not increase its productivity declines, *so too do the prices it must pay in order to obtain goods*. And thus its real income—its ability to obtain goods for the money it earns—does not fall at all!

Consider. The doubling of production by the members of the one group—let us call it Group A from now on—represents two things simultaneously: First of all, of course, a rise in its production relative to that of the other group—which from now on we call Group B—from 1:1 to 2:1. This is what is responsible for its proportion of total production rising from a half to two-thirds and for the proportion of Group B falling from a half to one-third. In virtue of the fact that total sales revenues and income are fixed at 1,000 units of money, it is responsible specifically for the revenue and income of Group A rising from 500 to 667 and for that of Group B falling from 500 to 333. But the second thing that the doubling of production by Group A is responsible for is an increase in the total production of the economic system in the ratio of 3:2. For a doubling of one-half of the output of the economic system plus the remaining initial one-half of the output of the economic system totals to three-halves of the initial output of the economic system.

Now, given the fact that the total expenditure to buy the output of the economic system is frozen at 1,000 units of money—which is why the total sales revenues and incomes of the economic system are frozen at 1,000 units of money—it follows that the purchase of three-halves the output entails a fall in prices to two-thirds of their initial level. *This fall in prices to two-thirds of their initial level is precisely equal to the fall in the revenue and income of the members of Group B*, inasmuch as the ratio of the 333 of revenue and income that the members of Group B now earn to the 500 of revenue and income that they initially earned is also equal to two-thirds. (At the same time, of course, the proportion of the total physical output of the economic system that is produced by the members of Group B, in falling to a third from a half, also falls precisely to two-thirds of its initial level. For when one divides a third by a half, the result is two-thirds.) Thus, while the members of Group B suffer a one-third decline in their money revenues and incomes as the result of the greater production on the part of the members of Group A, they simultaneously experience a one-third reduction in the prices they pay, and thus no reduction whatever in their actual buying power or so-called real incomes.

Could this amazing result be some kind of strange coincidence?

To find out, let us consider the results if the members of Group A were in fact to succeed in increasing their production ninefold instead of only twofold. In this case, the members of Group A would account for nine-tenths of the output of the economic system and earn 900 of the fixed 1,000 of total sales revenue and income. At the same time, the members of Group B would now account for only one-tenth of the output of the economic system and would accordingly earn only 100 of the fixed 1,000 of total sales revenue and income. In falling to one-tenth of the output of the economic system from one-half of the output of the economic system, the proportion of Group B's production to that of the economic system as a whole falls to one-fifth of its initial level, for that is the ratio of a tenth to a half. And, of course, the revenue and income of Group B, in falling to 100 from 500, falls to a fifth of its initial level.

To find out if our previous finding was a coincidence, we need only determine the extent to which prices fall in the present instance. If they too fall to one-fifth of their initial level, then we can be sure that more than a coincidence is involved.

It turns out that prices do fall precisely to a fifth of their initial level. This results from the fact that in increasing its production by a multiple of nine, Group A now produces an output equal to nine-halves of the initial output of the economic system. When added to the output of Group B, which is equal to one-half of the initial output of the economic system, the result is a total production that is equal to ten-halves of the initial output of the economic system. The fact that in the conditions of the case the ten-halves of the initial total output must be sold for the same fixed 1,000 of sales revenues requires that prices be two-tenths as great, which, of course, means that they are one-fifth as great. Thus, once again, the percentage fall in the revenues and incomes of the members of Group B is precisely matched by the percentage fall in the prices of the goods they buy, and thus, once again, the members of Group B suffer no decline in their real incomes.

The mathematical necessity of prices and the revenue and income of the members of Group B falling by the same percentage, and thus the real incomes of the members of Group B remaining the same, can be established as a universal principle. To do this, it is only necessary to state matters algebraically. Thus, let the initial output of Group A be expressed as O_A and that of Group B, as O_B . The total initial output of the economic system as a whole will then be represented simply as the sum of $O_A + O_B$. The initial proportion of total output produced by Group B will then be $\frac{O_B}{O_A + O_B}$. The initial relative production of the two groups in this case need no longer

be equal. It could be anything.

Now let us imagine that the members of Group A find a way to increase their production by any amount. Call it X . As a result of this increase in output by Group A, the proportion of total output produced by Group B falls to $\frac{O_B}{O_A + X + O_B}$ from $\frac{O_B}{O_A + O_B}$. When the former expression is divided by the latter, the two O_B terms constituting the numerators cancel out and the result is $\frac{O_A + O_B}{O_A + X + O_B}$. This is the measure of the fall in the sales revenues and incomes earned by the members of Group B. It is the ratio of their new, lower proportion of total production to their previous, larger proportion of total production.

It turns out that the fall in prices that results from Group A's increase in its production by amount X is also precisely equal to $\frac{O_A + O_B}{O_A + X + O_B}$. For the numerator of this

expression is the initial volume of total production and the denominator is the larger volume of total production that results from Group A's increase in its output by amount X . When production is $O_A + O_B$, the price level is the fixed 1,000 of spending divided by this volume of production. When production is increased to $O_A + X + O_B$, the price level falls to the fixed 1,000 of spending divided by this larger volume of production. The ratio of this new, lower price level to the initial price level is thus found by dividing $\frac{1,000}{O_A + X + O_B}$ by $\frac{1,000}{O_A + O_B}$. When this division is performed, the two 1,000 terms constituting the numerators cancel out, and the result stands as the ratio of the second denominator to the first, which is exactly the same as the ratio of Group B's new, lower sales revenue and income to its initial sales revenue and income.

The principle that has now been established is that under the conditions of a fixed quantity of money and volume of spending, the increase in production by any group acts equally to reduce the price level as well as the sales revenues and incomes of the members of the rest of the economic system.

We are not yet through with amazing results, however. The result of free competition and the inequality of revenue and income that results from it is that prices end up falling *by more* than the revenue and income of the members of Group B. This is because of the fact that in the process of competition the members of Group B will almost certainly succeed in increasing their production to some extent. They will be strongly aided in doing so by the operation of the pyramid-of-ability principle.

Thus, for example, imagine that Group A represents

10 percent of the producers and Group B, 90 percent. Assume that initially Group A produces 10 percent of the total product of the economic system and Group B, 90 percent of the total product of the economic system. Now imagine that under the freedom of competition, the members of Group A, who represent the most intelligent, ambitious, and hardworking individuals in the economic system, succeed in increasing their production by a multiple of nine. At the same time, imagine that the members of Group B succeed in doubling their production. (This doubling occurs as the result of the members of Group B having to compete with the members of Group A and thus improve their own performance, of being able to learn from the success of the members of Group A, and of being able both to work under the direction and with the aid of products and methods of production devised by members of Group A.)

As the result of these respective increases in production, the members of Group A now produce an amount equal to nine-tenths of the initial output of the economic system, for they have increased their output, initially equal to one-tenth the output of the economic system, by a multiple of nine. At the same time, the members of Group B now produce an amount equal to 1.8 times the initial output of the economic system, for they have doubled their nine-tenths of the initial output. Thus total production in the economic system as a whole is now 2.7 times its initial amount. The proportion of the total output produced by the members of Group B is now two-thirds— $1.8 \div 2.7$. It was initially nine-tenths. The fall in the proportion of output produced, and therefore of revenue and income earned, by the members of Group B is found by dividing two-thirds by nine-tenths. The result is $\frac{20}{27}$. Given 1,000 monetary units of total revenue and income in the economic system, the earnings of the members of Group B fall from 900 to 667.

Despite this fall in their money sales revenues and incomes, the members of Group B come out far ahead in this case in real terms. In fact, their real incomes precisely double, in full proportion to their increase in production. This is evident in the fact that total production in the economic system increases by a multiple of 2.7 and thus that prices fall to $\frac{10}{27}$ of their initial level. When the $\frac{10}{27}$ price level is divided into the $\frac{20}{27}$ money-revenue-and-income level of the members of Group B, the result is that the buying power—that is, the real revenues and incomes—of the members of Group B exactly doubles, just as their production.

Indeed, it should be obvious that it can be shown algebraically, as a general principle, that if Y is the amount of increase in the production of Group B, while X is the amount of increase in the production of Group A, then the real income of Group B increases in the ratio

of $\frac{O_B + Y}{O_B}$, at the same time that the real income of Group

A increases in the ratio of $\frac{O_A + X}{O_A}$. This result follows

from the fact that the change in a group's real income is equal to the change in its money income divided by the change in the price level. In an economy with an invariable money, the change in a group's money income is equal to the change in its relative contribution to production. Thus the change in the money income of Group B is equal to the ratio of its current relative contribution to production to its initial relative contribution to production. Its current relative contribution to production is

$\frac{O_B + Y}{O_A + O_B + X + Y}$. Its initial relative contribution to pro-

duction, of course, was $\frac{O_B}{O_A + O_B}$. When the first fraction

is divided by the second, the result is $\frac{O_B + Y}{O_B} \times$

$\frac{O_A + O_B}{O_A + O_B + X + Y}$. When this expression is divided by

the change in the price level, which also equals

$\frac{O_A + O_B}{O_A + O_B + X + Y}$, the result simplifies to $\frac{O_B + Y}{O_B}$. Ex-

actly the same procedure establishes the fact that the real income of Group A changes in the ratio of $\frac{O_A + X}{O_A}$.

Thus, the entirely benevolent nature of economic competition and the economic inequality that results from it has now been demonstrated in the context of an invariable money. It should scarcely be necessary to say that the only difference that is made by an increase in the quantity of money more or less in pace with the increase in the volume of production is that in those conditions the money revenue and income of the members of any Group B would not decline and would actually tend to increase to the extent that the members increased their production. Under these conditions, of course, prices would no longer tend to decline.

It should also scarcely be necessary to say that in the course of economic progress, the members of any Group B would have to be prepared to change their occupations. They could not, for example, rationally expect to go on producing horses and buggies once members of Group A have introduced the automobile. Their same or greater production would have to be in the context of their making the necessary adjustments in what they produced.

Notes

1. Cf. Ludwig von Mises, *Socialism* (New Haven: Yale University Press, 1951), pp. 40–42; reprint (Indianapolis: Liberty Classics, 1981). Page references are to the Yale University Press edition; pagination from this edition is retained in the reprint edition.

2. For a discussion of its influence on the mentality of destructionism, see above, pp. 230–231.

3. Cf. von Mises, *Socialism*, pp. 500–504.

4. See above, p. 174. This, of course, is a leading theme of von Mises.

5. See above, pp. 201–212.

6. See above, pp. 275–278 and 288–290.

7. For elaboration of the significance of this fact, see below, pp. 477–480. See also below, pp. 632–634.

8. See below, pp. 622–642, especially pp. 622–629. So intimately connected is the present discussion with that just referenced, that it would almost certainly be worthwhile to reread it after having read that material.

9. See below, pp. 631–632 and 824.

10. Even if a rise in costs comes out of above-average profits earned by the producers, and thus does not raise the price of the product they are selling, it still operates to make that price higher than it would have been in the long run, because now competition will not be able to reduce the price to the extent that it otherwise would have. In addition, whatever portion of that profit would have been used for reinvestment, either in this particular branch of production or anywhere else in the economic system, is now no longer available. Thus production will

be held back in the lines which are deprived of this additional capital and prices will be made higher than they otherwise would have been in this respect too.

11. On this point, see below, pp. 634–636. See also above, pp. 98–99.

12. See below, pp. 622–642. See also below, pp. 462–473 and 480–482, which explain the productive functions of businessmen and capitalists. The meaning of productive expenditure, incidentally, is expenditure for the purpose of making subsequent sales; it is the expenditure of business enterprises for business purposes. See below, pp. 444–445, for elaboration.

13. This is apart from instances in which business or investment losses are incurred, which the capitalists certainly strive to avoid but which are capable of wiping out one's entire capital, and more.

14. Matters are different when an individual acquires a possibly substantial sum of wealth that he does not regard as essential to his livelihood or to the provision for his future needs and wants. In such cases, he probably goes through that wealth fairly quickly. Even though the wealth in question may be thought of as capital to the extent that it is temporarily invested and earns a rate of return, the behavior of such individuals should not be thought of as at all typical of that of capitalists. Insofar as individuals behave in such a way, they certainly are not capitalists for very long.

15. The figure of the significant-sized capitalists' consumption being not much more than 10 percent of total consumption is consistent even with the sum of all profit and interest incomes

being 30 percent of national income, while the sum of all wage and salary incomes is 70 percent of national income (national income being the sum of both such categories of incomes). It is consistent if the significant-sized capitalists own approximately 75 percent of the capital of the economic system and earn approximately 75 percent of the profit and interest incomes, and then save half of their incomes and consume half of their incomes. On these assumptions, the incomes of the significant-sized capitalists represent 75 percent of 30 percent of national income, that is, 22.5 percent of national income; their consumption of half of their incomes thus represents a consumption of 50 percent of 22.5 percent of national income, that is, 11.25 percent of national income. When that 11.25 percent is divided by the approximately 85 percent of national income that can be assumed to be expended for consumption as distinct from net investment, the result is a consumption expenditure on the part of the significant-sized capitalists of about 13 percent of total consumption expenditure.

16. For a discussion of the same subject from the perspective of the very limited extent to which wage rates in particular might conceivably be raised, see below, pp. 650–653.

17. And, indeed, if it could be gained, a significant portion of the 10 percent would come at the expense of such things as support of education, the arts, and other charitable activities.

18. Ludwig von Mises, *Human Action*, 3d ed. rev. (Chicago: Henry Regnery Co., 1966), p. 531.

19. See Simon Kuznets, “Long-Term Changes in the National Income of the United States of America Since 1870” in Simon Kuznets, ed., *Income and Wealth of the United States* (Baltimore: The Johns Hopkins Press, 1952), pp. 82, 86. See also Paul Samuelson and William Nordhaus, *Economics*, 13th ed. (New York: McGraw-Hill Book Company, 1989), p. 860.

20. The degree of capital intensiveness is indicated by the ratio of accumulated capital to national income as well as by the ratio of accumulated capital to current consumption expenditure mentioned earlier in this chapter. This is because national income and consumption expenditure are necessarily always very closely related—indeed, are almost equivalent concepts. (Concerning the relationship between national income and consumption, see below, pp. 699–706.) For additional measures of the degree of capital intensiveness, see below, p. 631.

21. See below, pp. 631–632 and 824.

22. For elaboration, see below, pp. 622–629.

23. For elaboration of this point, see below, pp. 737–739.

24. For a discussion of the destructive consequences of inheritance and income taxes, see below, pp. 306–310. See also pp. 636–639, 653–655, and 826–829. For a critique of land reform, see below, pp. 317–322. For further critiques of redistributionism, namely, of its role in the interpretation of the economic history of capitalism and as a leading aspect of welfare statism, see below, pp. 642–663.

25. On the significance of profit-and-loss incentives, see above, pp. 172–183, especially 176–180. Concerning the lack of individual initiative and the freedom of competition under government ownership, see above, pp. 275–278.

26. The destruction of the special gains of ownership is actually a consequence of redistributionism in general, and one that is especially noteworthy in the context of a non-division-of-labor society. For as soon as it is realized that redistributionism is to be a *system*, not only do people stop accumulating or maintain-

ing wealth, thus leaving very little for the recipients of “redistributions” to receive, but also what the recipients do receive can give them no pleasure, in that they know that they themselves will in turn suffer expropriation.

27. Even if the taxpayers have the power, in their capacity as voters, to remove the elected officials, they are unlikely to be able to use that power. Obviously, there is no question of such power insofar as relatively small numbers of high-income taxpayers are plundered by majorities. Insofar as tens of millions of taxpayers are made to foot the bill for the losses of nationalized enterprises, the losses of any given such enterprise are rendered too small to impel the individual taxpayer to action. A hundred million taxpayers who must pay \$10 or \$20 more in taxes to cover the losses of this or that government enterprise are no match in terms of motivation and organization for the pressure-group members, who as individuals gain very substantially from the government enterprise’s losses.

28. Amazingly, none other than Adam Smith appears to hold this view. See below, pp. 476–477, where I quote him precisely to this effect.

29. This discussion is closely related to the critique of the doctrine that money is the root of all evil, which I presented earlier. See above, pp. 143–144.

30. Cf. Ludwig von Mises, *Bureaucracy* (1944; reprint, New Rochelle, N. Y.: Arlington House, 1969), pp. 20–39.

31. *Ibid.*, pp. 40–63.

32. *Ibid.*

33. *Ibid.*, pp. 64–73.

34. As further illustration of the bureaucratization of business, see above, pp. 196–199, where government-made obstacles to the operation of profit management are described as standing in the way of the achievement of fair treatment of blacks.

35. See above, pp. 234–237 and 254–256.

36. For the proof of these points, see below, pp. 618–642, especially 622–629 and 631–632. See also p. 824.

37. The reason such expenditures, when undertaken by the government, do not represent capital formation is explained below, on pp. 454–455.

38. Again, see below, pp. 631–632 and 824.

39. See below, pp. 618–642, for a comprehensive explanation of how capital accumulation is achieved and how it raises real wage rates.

40. See below, pp. 622–629 and 632–634.

41. Once more, see below, pp. 622–629 and 824.

42. See above, p. 147. See also, below, pp. 741–743.

43. For an explanation of how innovation, and anything else that increases efficiency, is a source of capital accumulation, see above, the example of the more efficient farmer, on pp. 132–133, and below, pp. 629–631 and 634–636.

44. Yet once again, see below, pp. 631–632 and 824.

45. Even if the effect is not to raise wage rates, but, in raising the demand for labor, to reduce or eliminate unemployment, that too operates to increase the funds available to the average wage earner—by virtue of reducing what he must pay to support the unemployed.

46. See below, pp. 618–642.

47. Cf. Touche Ross & Co. AB, *Tax & Investment Profile Sweden* (New York: Touche Ross International, 1985), pp. 5–6, 34.

- tion, 3d ed. (London, 1821), chap. 2; reprinted as vol. 1 of *The Works and Correspondence of David Ricardo*, ed. Piero Sraffa (Cambridge: Cambridge University Press, 1962), pp. 67–69. (Where appropriate, from now on, specific page references to the Sraffa edition will be supplied in brackets.)
49. *Ibid.*, pp. 70–71.
50. See above, pp. 67–69.
51. Cf. Ricardo, *Principles of Political Economy and Taxation*, chap. 5, [p. 93].
52. *Ibid.* [pp. 94–95.]
53. See *ibid.*, chap. 24, [pp. 203–204].
54. Hopefully, it is not necessary to say that these numbers are to be understood merely as representative, not as describing the actual total agricultural output or total produce rent of the country. To do that, they would need to be multiplied perhaps by a factor of several hundred thousand or several million, depending on the number of units of land involved.
55. Interestingly, Ricardo was very much aware of these possibilities. See *Principles of Political Economy and Taxation*, chap. 2 [pp. 78–83].
56. See below, pp. 358–367.
57. See above, p. 69.
58. Justification for the use of quotation marks around the word “owners,” if not already understood, will become clear in the next part of this chapter. See below, pp. 331–332.
59. See above, pp. 63–71.
60. See above, pp. 66–67, 98, and 234–237.
61. For a discussion of how the rise in land rents caused by environmentalism comes at the expense of the demand for labor, see below, pp. 667–668.
62. See above, Chapter 1, n. 38.
63. The problems in the way of assimilation are a matter that needs historical investigation. They evidently continue even down to the present time, with the continued existence of Indian “reservations.” The logically necessary intertribal warfare of the Indians, and all other primitive peoples, is also a matter worthy of historical investigation and dissemination to the public, which is increasingly under the sway of doctrines extolling the life of primitive peoples and attacking the life of modern, Western man.
64. Cf. von Mises, *Socialism*, pp. 55, 375.
65. What is present here, of course, is the operation of time preference, which renders a given sum in the present more valuable than a larger sum in the future. See above, pp. 55–58.
66. See below, pp. 931–933.
67. On these points, cf. von Mises, *Human Action*, pp. 684–688, 823–824; *Socialism*, pp. 225–226.

91. *Ibid.*
92. *Ibid.*
93. *Ibid.*
94. This latter hypothesis is supported by the profound mental weakness displayed above all by the supporters of environmentalism. See above, pp. 107–112. See also above, pp. 332–336.
95. See above, pp. 42–45 and 59–61.
96. See below, pp. 580–594 *passim* and 938–942.
97. See, above, pp. 196–199 and, below, pp. 382–384. See also George Reisman, *Capitalism: The Cure for Racism*, pamphlet (New York: *The Intellectual Activist*, 1982); reprinted (Laguna Hills, Calif.: The Jefferson School of Philosophy, Economics, and Psychology, 1992).
98. See above, p. 144.
99. Cf. von Mises, *Human Action*, pp. 273–276; *Socialism*, pp. 319–321.
100. For a confirmation of the above analysis in terms of the operation of Say’s Law, see below, 561–569.
101. Cf. von Mises, *Human Action*, pp. 159–164; *Socialism*, pp. 294–295.
102. Cf. Ayn Rand, *Atlas Shrugged*, pp. 1063–1065.
103. See again the last two notes to von Mises and the preceding reference to Ayn Rand.
104. See below, pp. 559–594.
105. Again, see above, pp. 42–45 and 59–61.
106. Cf. von Mises, *Human Action*, pp. 159–161.
107. Cf. Ayn Rand, *Atlas Shrugged*, pp. 1064–1065.
108. Cf. von Mises, *Socialism*, pp. 315–319.

109. Cf. Adam Smith, *The Wealth of Nations* (London, 1776), bk. 1, chap. 3; reprint of Cannan ed. (Chicago: University of Chicago Press, 2 vols. in 1, 1976), 1:17–25. See also Frederic Bastiat, *Economic Harmonies*, trans. W. Hayden Boyers (New York: D. Van Nostrand & Co., 1964), pp. 561–567.

110. It is important to recall that the extension of the division of labor in this way requires the availability of more capital. There must be the appropriate additional supplies of plant and equipment and materials, as well as the larger number of workers. See above, p. 141.

111. Cf. below, pp. 542–580 passim.

112. Cf. von Mises, *Human Action*, p. 128; Ayn Rand, *Atlas Shrugged*, pp. 1064–1065.

113. See above, pp. 123–125.

114. For an account of how more rapid technological progress contributes to capital accumulation, see below, pp. 629–631.

115. See above, pp. 358–362 and 313–316.

116. On these points, see below, pp. 622–629 and 709.

117. For a discussion of the causes of capital accumulation and how it is promoted by anything which increases the efficiency of production, see below, pp. 634–636.

118. Cf. *Income and Wealth of the United States*, p. 82. (Raymond Goldsmith indicates a significantly lower range. See *ibid.*, p. 297.) In contrast with the previous estimates cited of the ratio of capital to national income in that period, which estimates included the value of land in capital, capital is here

presented simply as the value of structures and producers' equipment, exclusive even of the value of business inventories. However, it is doubtful that the inclusion of business inventories would make the capital-output ratio significantly larger.

119. The use of these percentages is based on the fact that two-thirds of an increase of 1½ percent of the population as a whole is 1 percent of the population as a whole and 2 percent of half the population. Likewise, one-third of the 1½ percent increase in the population as a whole is ½ percent of the population as a whole and 1 percent of half the population.

120. On this essential point, see below, pp. 634–636.

121. See below, *ibid.*

122. I deal with the vital subjects of unemployment and the determinants of the average worker's standard of living—his real wages—throughout Chapters 13 and 14, below. See also pp. 938–942.

123. Actually, of course, the quantity of gold that has been mined is probably as small compared with the quantity that remains to be mined as is the quantity of most other minerals that has been mined compared with the quantity of them that remains to be mined. As I have shown, in reality, the useable, accessible supply of everything, even including gold, can be indefinitely increased by virtue of man enlarging his knowledge of and physical power over the world and the universe. See above, pp. 63–66.

124. See below, pp. 503–506 and 517–526.

CHAPTER 10

MONOPOLY VERSUS FREEDOM OF COMPETITION

1. The Meaning of Freedom and of Freedom of Competition

If there is anything for which capitalism is more strongly denounced than its competition, it is its alleged *lack* of competition and tendencies toward monopoly. These denunciations stem in large part from a failure properly to understand the meaning of freedom of competition and of monopoly. The terms are usually understood in the light of the anarchic rather than of the rational concept of freedom.¹

According to the rational concept of freedom, of course, freedom means *the absence of the initiation of physical force*—in particular, on the part of the government. Viewed in a positive light, freedom is the freedom to *do* whatever one is otherwise capable of doing, unconstrained by the initiation of physical force.

Applied to the realm of competition, if a man possesses only a few thousand dollars of capital or no capital at all, freedom of competition for him does not mean the ability to enter into competition with General Motors. It *does* mean the ability to do whatever he is capable of doing with the few thousand dollars of capital he has (or with his abilities unaided by any capital)—without being stopped by the government. It means, for example, that if he can afford to buy a taxicab or a liquor store and judges that that is what is best for him to do, he will not be stopped from doing it by licensing laws. It means that if he is capable of working at a job and can find an employer willing to hire him, he will not be stopped from working by minimum-wage laws or by laws giving co-

ercive powers to labor unions—in both of which cases a part of the supply of labor is forced into unemployment by wages rates being forcibly raised above the market level. And if a man (or a company) does have the capital required to compete with General Motors, and wishes to compete, freedom of competition means for him that he will not be stopped by a tariff or by antitrust laws preventing mergers and the growth of big business. It means, for example, that Toyota and Nissan will not be stopped and that if U.S. Steel, Exxon, Boeing, or IBM want to enter the automobile business, they will not be stopped.

Freedom of competition does not mean that one is automatically able to compete—that one automatically has the necessary knowledge, capital, or whatever else may be required to compete. It means only that insofar as one *does have the means of competing*, one will not be stopped from exercising those means by the initiation of physical force.

The fact that freedom of competition does not guarantee that one will be able to compete—the fact that freedom in general does not guarantee that one will be able to do whatever it is one would like to do, because freedom does not by itself supply the necessary means—does not reduce freedom to the status of a trivial luxury capable of being enjoyed only by the wealthy, as the Marxists claim. Freedom, including the freedom of competition, is a vital necessity for everyone. It means, in essence, *the freedom of opportunity*—the freedom to exploit the opportunities one already has, and so later on be capable of enjoying greater opportunities.² It means, for example, that an impoverished black youth is able to

take a low-paying job, if that is the best he can find, and then with the experience and skill he gains from that job go on to something better. It means that he is able to keep the income he earns from that job and, if he wishes, save it to buy a taxicab or any other kind of business he can afford and so further increase his ability to earn money. Freedom, thus understood—as the freedom of opportunity—is vital to everyone.³

Not only does everyone need freedom for himself, but he also needs freedom for others because he enormously benefits from their freedom. Everyone in the world is vastly more prosperous because Thomas Edison and Henry Ford and all the other great inventors and industrialists had the freedom to implement their ideas and bring their products to the market. The general gains from the freedom of lesser men are no less real.⁴ For example, there is a gain to everyone who uses such services as those of barbers and tailors if those best able to provide such services are free to provide them. The freedom of all is a condition in which every industry can be carried on by those best suited in the world to conduct it. It is a condition in which each can be supplied by the best choice of suppliers. This, indeed, is the meaning of the freedom of competition: *that every industry and occupation should be legally open to everyone who judges that he is equipped to succeed in it and who wishes to try and that then the buyers should be free to choose among them.*

High Capital Requirements as an Indicator of Low Prices and the Intensity of Competition

In connection with this discussion, it should be realized that the existence of high capital requirements as a condition for being able to compete does not constitute a “barrier to entry” in any legitimate sense, despite the frequency of the claim that it does. The fact that in present conditions it may take a billion dollars or more to build a competitive-sized automobile factory or steel mill does not represent a violation of the freedom of entry or competition. On the contrary, it is the result of the fact that in order to be profitable, it is necessary to produce at low costs, thanks precisely to the freedom of competition. The high capital is necessary only in order to produce on a large scale and with the use of capital-intensive methods of production, both of which are means of achieving low costs of production. If the achievement of low costs of production were not necessary, then neither would be the substantial sums that must be invested to reduce costs. High capital requirements would not exist.

What makes it necessary to achieve low costs of production is the fact that others, who employ large sums of capital and who thereby achieve low costs of produc-

tion, sell at correspondingly low prices, which makes it impossible to succeed in the business while producing at the high costs resulting from the lack of sufficient capital. In the simplest possible terms, the high capital of General Motors and the other major automobile companies does, indeed, stop people with capitals as limited as those of neighborhood grocers from producing automobiles. This is as it should be. In order for people to be able to succeed in the automobile business with such limited capitals, automobiles would have to be produced without the aid of substantial machinery or the use of such things as moving assembly lines (which require a very large volume of output). As a result, they would have to be produced at an extremely high cost, comparable to the cost that existed in the early years of the industry. And thus they would have to sell at correspondingly high prices.

It also follows from this discussion that in order to achieve the competitive advantages of the possession of a large capital, a firm *must* sell at prices that reflect its low costs of production. If it does not, then it opens the door to firms with smaller capitals and higher costs of production, that can then succeed in the business and possibly accumulate the capital necessary themselves to achieve the lower level of costs. Thus, high capital requirements are the result of the freedom of competition, which results in low costs of production and low prices, and which necessitates the possession of a substantial capital where that is the means of achieving low costs and low prices.

High capital requirements are an illustration of the principle that under the freedom of competition and the freedom of entry the only way one keeps others out of a field is by producing better and more economically. Where the freedom of competition and the freedom of entry are violated, on the other hand, it is the better, more economical producers, including those with larger capitals, who are kept out—by means of the initiation of physical force.

2. The Political Concept of Monopoly and Its Application

Consistent with the concepts I have expounded of freedom in general and of freedom of competition in particular, is what I call *the political concept of monopoly*. According to the political concept of monopoly, *monopoly is a market, or part of a market, reserved to the exclusive possession of one or more sellers by means of the initiation of physical force by the government, or with the sanction of the government.*

Monopoly exists insofar as the freedom of competition is violated, with the freedom of competition being

understood as the absence of the initiation of physical force as the preventive of competition. Where there is no initiation of physical force to violate the freedom of competition, there is no monopoly. The freedom of competition is violated only insofar as individuals are excluded from markets or parts of markets by means of the initiation of physical force. Monopoly is thus a market or part of a market reserved to the exclusive possession of one or more sellers by means of the initiation of physical force. It is thus something *imposed* upon the market from without—by the government. (Private individuals—gangsters—can initiate force to reserve markets only if the government allows it and thereby sanctions it.)

Thus, monopoly is not something which emerges from the normal operation of the economic system, and which the government must control. That mistaken view is based on the *economic concept* of monopoly, which will be considered later in this chapter. The economic concept of monopoly is the corollary of the anarchic concept of freedom and its implication that private individuals can violate the freedom of speech or press by their mere refusal to provide others with the material means for spreading their ideas and can violate the freedom of competition by virtue merely of their possession of larger capitals and superior abilities.⁵ Rationally understood, monopoly is external to the normal operation of the economic system and is, as I say, imposed by the government or with the government's sanction. It is, as it was originally understood, an exclusive grant of government privilege, such as was extended by English monarchs in earlier centuries to the British East India Company and to various guilds of producers or merchants.

As subsequent discussion will show, the leading examples of monopoly rationally understood, that is, according to the political concept of monopoly, are exclusive government franchises, licensing laws, tariffs, the operation of minimum-wage and prounion legislation, government-owned or government-subsidized enterprises, a socialist society, and, however surprising, the antitrust laws.

Monopoly Based on Exclusive Government Franchises

Exclusive government franchises reserve markets to the exclusive possession of the holders of the franchises, and do so by means of the government's initiation of force. Leading examples of this category of monopoly are electric, gas, and water service, cable television, local telephone service, and, in many localities, local bus service. In each case, no one but the holder of the government's franchise is legally allowed to sell the service in question in the particular market. Anyone else who might wish to sell the service in that market is

stopped by law and the threat of physical force that stands behind the law. Since the provision of such service does not represent an act of force, stopping its provision by means of the use of force represents an *initiation* of force—an act of aggression—on the government's part.

In connection with monopoly in the form of exclusive government franchises, what is essential is not the fact that there is only one supplier. There might well be just one supplier in these cases under the freedom of competition. What is essential to monopoly is that physical force is initiated in order to keep out of the market sellers who might otherwise wish to be in it—that the determination of the fact that there is just one seller, and which particular one seller, is made by means of the initiation of physical force, not by the freedom of competition. Under the freedom of competition, Alcoa was for many years practically the only seller of aluminum ingot in the United States. Nevertheless, it was *not* a monopoly, according to the political concept of monopoly. This was because its position did not rest on the initiation of physical force, but on its ability and willingness to produce and sell its aluminum at prices that were profitable to it, but yet too low for any potential competitor to be profitable.

It is possible, indeed, likely, that economies of scale associated with most or all of the cases presently falling under the category of exclusive-government-franchise monopoly would make possible a situation similar to that of Alcoa. Like the case of Alcoa, a single electric or gas company providing service in a given area would not constitute a monopoly, if, in order to be in that position, it offered its customers lower rates than any other potential supplier offered. What would be crucial is that under the freedom of competition, precisely this is what it would have to do, if it wished to be the sole supplier. Indeed, in order to become the sole supplier, it would almost certainly have to offer its customers *contractual guarantees* concerning its rates, so that they would not have to fear temporary arbitrary increases in the period in which competitors did not yet have the time required to enter the field. In other words, to become the sole supplier of gas or electricity and so forth, under the freedom of competition, a firm would have to offer a long-term, contractually guaranteed price that was below what its potential competitors were prepared to offer.

To guard against possible misunderstanding, it is necessary to say explicitly that exclusive *private* franchises, such as the right to own and operate a Coca Cola bottling plant, or a McDonald's hamburger restaurant, do not represent any kind of initiation of force. The name and formula of Coca Cola and the name, supplies, and counseling provided by McDonald's are the private property

of these concerns, and thus they have the right to determine who is and who is not to receive the use of that property. It would be an initiation of force—theft—for anyone to use that property against their will.

The government, on the other hand, should not own any property whose use it may give to some and withhold from others, because it is properly nothing more than the agent of the people—of each and every person equally. Apart from what is required for such things as police stations, courthouses, and military bases, which are necessary for the carrying out of its rightful and strictly delimited functions, it certainly should not, and for the most part does not, own the land of the country. The citizens individually and in private voluntary associations are properly the owners of the land and all that is upon it. They alone have the right to determine who can and who cannot use their private property. In denying anyone the right to undertake economic activity, the government simply initiates the use of force.

Licensing Law Monopoly

Licensing laws create monopolies by virtue of initiating force to reserve markets to the exclusive possession of the license holders. Examples of monopoly based on licensing laws are the occupations of accountant, barber, beautician, contractor, dentist, lawyer, liquor store owner, optician, pharmacist, physician, psychologist, teacher, and taxicab driver. Only the holders of the licenses are legally allowed to pursue the field in question. All others are excluded by means of the initiation of physical force.

Of course, licensing laws are defended, on the grounds that they are necessary to public health or safety, or some other such high purpose. But the fact is, they keep out of fields suppliers who otherwise would be in them—suppliers with whom the public would be glad to deal voluntarily, without any form of force or fraud being present. Their effect is always to deprive the buyers of services they could have had, to raise the price of the services they are allowed to receive, to elevate the incomes of the license holders, and to depress the incomes of those who are excluded from the licensed fields and forced to crowd into other, less-well-paying fields.

It may well be the case that licensing sometimes does serve, as its supporters often claim, to raise the minimum level of competence and expertise in a field and thus to guarantee to the buyers a higher level of service than they would have received in its absence. But even if this is true, it is not by any means an advantage to the buyers. It merely means, in many cases, that buyers are forced to buy a higher level of service than they want or need and, if they cannot afford the higher level of service, are forced to do without the service they could have had. The result on this score is comparable, in essence, to a law

that would require that the minimum quality of automobiles on the road be no less than, say, that of a five-year-old Chevrolet of average quality. While such a law would undoubtedly raise the average quality level of the cars that remained on the road, it would also operate to prevent many people from driving—namely, those who could not afford anything beyond the quality of the cars they presently drove and whose cars were below the quality of the average five-year-old Chevrolet.

In just this way, medical licensing—the field in which licensing might be thought to be more necessary and proper than in any other—has the paradoxical effect of depriving the poor of medical care altogether.

In the absence of medical licensing, it would not be the case that barbers and butchers would be able to compete as doctors, any more than they can compete in the automobile or steel industry. Competition would establish educational, performance, and other requirements. And it would still be fraud to claim a degree, or any other form of private certification, that one did not have. The new competition in medicine would come from people who today must be content to be registered nurses, pharmacists, paramedics, biologists, and so forth, but who could become qualified to practice important aspects of medicine presently monopolized by the licensed physicians, and do so with a high degree of competence.

These people are present in the ranks of those arbitrarily rejected by today's monopolistically restricted medical schools, or who are deterred from even trying for admission to today's medical schools. They would be able to provide medical care to many who today cannot afford medical care, and even if the medical care they provided was less complete than that provided by most of today's practitioners, it would certainly still be far superior to no medical care at all. Moreover, in serious cases beyond their competence, they could make referrals to doctors of greater expertise than themselves. At the same time, in necessary cases, the poor would be better able to afford the services even of the more qualified doctors, since those services too would be rendered less expensive by the new competition. For many people who had had to use them would also turn to the less expensive services of the new competitors to varying degrees. This would operate both to reduce the price of the more qualified doctors' services, bringing them more within reach of the poor, and to make their time more available to the poor, since it would no longer be in as great demand by the middle class and the wealthy.

In many cases, licensing actually serves no legitimate purpose whatever. It is nothing more than a pretext for imposing arbitrary requirements on prospective suppliers, its only real purpose being to keep the supply down

and the price up. For example, requiring barbers and beauticians to take year-long courses on dermatology can have no other purpose but to discourage people from becoming barbers or beauticians and thus to keep up the price of the services of those who do become barbers or beauticians.

Where, as in medicine, and even in home building, there is a legitimate purpose in licensing, that purpose can be achieved without licensing. People want to know with whom they are dealing. That is why they attach so much importance to brandnames and why customer good will is so important. In dealing with doctors and home builders—especially if they could not take for granted the approval of an allegedly all-wise, all-knowing government, bestowed through the conferral of a license—people would insist on an established reputation or on strong endorsements from those with established reputations and whose judgment they trusted. And, of course, insurers (and in home building, lenders as well) could impose their own, additional requirements. Indeed, it is even possible to imagine that the very same employees of the present medical licensing boards, and the very same building inspectors who now work for the government, would stay on as employees of private certification agencies and continue to perform all the legitimate substance of the work they presently perform.

There would be one essential difference, however, that would constitute a fundamental and major improvement. That would be that no one would be compelled to accept the judgment of government officials or of any other group of people. With private certification, not only would the supply of a service be greater and the price correspondingly lower, but, no less important, there would permanently be more chances for new ideas being tried, and thus improvements would come far more rapidly than is possible today. Under private certification, not only would there almost certainly be more than one certification agency in any given occupation, but the individual would always have the right to step outside the system and decide entirely for himself. It would not be necessary, as is now the case, that before trying a new cure for a disease, or a new method of constructing a building, a person would have to wait upon the pleasure of any group of government officials to approve it. If, to take a particularly outrageous example, a person has heart disease, or has suffered a stroke, he could freely buy medications whose effectiveness has already, long-since been proved in Western Europe, to the satisfaction of large numbers of American doctors. Neither he nor his physician would have to fear the licensing power either of a state's medical licensing board or of the federal government's Food and Drug Administration. If an individual is dying of cancer, and cannot be cured by meth-

ods endorsed by the present medical establishment, he could freely accept the responsibility of turning to something different.

It is no doubt true that under the freedom of competition, some individuals would act irresponsibly and at the first opportunity turn to quacks. The existence of such people, however, is no reason for denying freedom to everyone else, who would use it to great advantage. Moreover, under freedom, stupidity of choice serves as its own punishment!

If the misuse of freedom by the ignorant and the foolish is what is feared, then a better case can be made for the licensing of politicians and government officials than of doctors or the members of any other profession or trade. This is because here, when people turn to charlatans, the consequences are suffered by all. But, of course, there can be no such thing as the licensing of politicians and government officials, for who would license them, but other politicians and government officials? And what could be more dangerous than to allow politicians and government officials to have such power?

The existence of freedom carries with it the possibility that people will make wrong and even foolish choices. But there is no alternative. That possibility exists *with or without freedom*. The great advantage of freedom is that each individual has the right to make his own choices and need not be bound by the ignorance or stupidity of others. The alternative to freedom is settling matters by force, and here the ignorant and the stupid have the greatest chance to control the outcome and to compel all to go with them. Indeed, the use of force is the only way that those who are knowledgeable and intelligent can be made to follow the lead of those who are ignorant or stupid. The choice, in other words, is not one between people making foolish choices on their own when they live under freedom and wise choices when they live under the control of government officials. The real choice is between at least those who are intelligent and wise making wise choices under freedom, and thereby setting an example for all others to follow, and those who are intelligent and wise being compelled to follow the will of the ignorant and stupid when the initiation of physical force takes the place of freedom.

The premise of a free country is that the citizens are intelligent enough to run their own affairs and, in the time left over from their own affairs, the affairs of their government as well. Citizens who are not qualified to pass judgment on the qualifications of their doctor or building contractor (or on the qualifications of the experts whose advice they accept) are even less qualified to pass judgment on matters of foreign policy or domestic policy. This is certainly not a plea to deprive such citizens of the right to vote—for the reasons just explained (though

it certainly can be taken as a good argument for limiting the questions that people have the power to decide by vote, that is, as an argument for limited government). On the contrary, it is a plea simply that people retain and enlarge their freedom of choice in the economic area and, by the natural method of gaining from their right choices and suffering from their wrong choices, be led to make all of their decisions as conscientiously and as wisely as they can.

Before leaving the subject of licensing monopoly, it is necessary to observe that probably far more important than breaking the licensing monopoly presently enjoyed by physicians would be breaking the licensing monopoly presently enjoyed by hospitals. People justly complain of the enormous costs of hospital stays. These costs could be radically reduced by allowing the freedom of competition in hospital care. The cost of hospital stays to patients is enormously higher in many cases than corresponds to the actual cost to the hospitals of providing their services. A thousand dollars a day for a hospital stay is often far out of line with the hospital's own costs that are necessary to provide the service together with an allowance for a competitive rate of profit. Under the freedom of competition, physicians and profit-seeking hospital administrators would be free to cash in on the high profits that could be made by opening their own hospitals. They would be free to concentrate on offering the presently most profitable types of care. The effect would be a decline in the price of such hospital stays to a point corresponding to the actual costs of providing them together with an allowance for the going rate of profit. At the same time, the freedom of competition would permit hospitals to cut their costs of operation and thus to bring rates down to levels reflecting still lower levels of actual cost.⁶

Today there is a great deal of justified outrage over the enormous and ever increasing cost of medical care, and, in response, people assert a right to medical care. But their idea of a right to medical care is a right consistent with the anarchic concept of freedom, that is, an alleged right which is to be implemented without regard to the willingness of others to cooperate. The government is to take money from the taxpayers, at the point of a gun, to implement this alleged right to medical care and it is to hold a gun to the heads of physicians and hospitals to make them supply medical care on the terms and by the methods it imposes. This is a total corruption of the concept of rights. It is, as Ayn Rand would describe it, the assertion of an alleged right to enslave.⁷

What needs to be done to solve the medical crisis is to understand the concept of the right to medical care consistently with the rational concept of freedom and the political concept of monopoly. The right to medical care

rationality means *the right to all the medical care one can afford to buy and chooses to buy from any willing provider*.

The medical crisis exists because of a repeated pattern of violation of the right to medical care properly understood. Individuals want to buy medical services from willing providers whom the government excludes from the medical professions by licensing laws. It violates the right of these individuals to buy, and of these providers to sell, medical care. Thus the government monopolizes the medical profession on behalf of its license holders. This makes medical care scarcer and more expensive. The government practices the same policy of exclusion and monopolization in the case of hospitals, again making medical care scarcer and more expensive. The government does exactly the same thing in the case of medications, through the Food and Drug Administration, which creates a systematic monopoly of the drugs and treatment methods it approves by forcibly excluding from the market all other drugs and methods of treatment.

The violations of freedom and individual rights practiced by the government in the pursuit of its policy of medical monopoly are powerfully reinforced by its policy of violating freedom and individual rights in forcing some citizens to pay for the medical care of others. In the face of pervasive monopoly, the policy of pouring ever more taxpayer money into medicine simply represents steadily enlarging the demand in the face of an artificially restricted supply, with the inevitable result that prices continually rise. This process is further powerfully compounded by the fact that medical care is made substantially or even entirely free to large numbers of recipients, who then have no reason to limit the amount of it they use, which, of course, leads to correspondingly large government expenditures to pay for it and to higher rates for paying patients, to whom a substantial part of the burden is shifted.⁸

The solution to the medical crisis is not the implementation of a vicious alleged right to medical care whose actual meaning is a right to enslave, but the implementation of the rational right to medical care. That is, to *end the government's policy of medical monopoly* (and, of course, its policy of forcing some citizens to pay the medical bills of others). It is to make the government recognize the citizen's actual right—his rational right—to obtain medical care from any willing provider and thus to stop the government's forcible exclusion of willing providers from the market.⁹

Tariff Monopoly

Protective tariffs represent the use of force to make foreign producers sell their goods at a higher price than domestic producers and/or less profitably than domestic

producers. As such, they represent legislation on behalf of monopoly, in that they attempt to reserve the market, or a larger share of the market, to the exclusive possession of domestic producers.

Protective tariffs (and licensing laws) highlight the fact that monopoly, according to the political concept, is not limited to the case of sole producers protected by the initiation of physical force. It applies equally to cases of *very large numbers* of producers whose market is protected by the initiation of physical force. A tariff monopoly can serve to protect tens of thousands of small, inefficient domestic producers against foreign competition. For example, a protective tariff on wheat in France has the effect of giving a monopoly of the French wheat market, or of a larger share of that market, to French wheat growers. The monopoly of these producers is no less a monopoly merely because of their large number. The market, or their part of the market, is reserved to them by means of the initiation of force. More efficient foreign producers are correspondingly denied the freedom of competition.

The Monopolistic Protection of the Inefficient Many Against the Competition of the More Efficient Few

Both tariffs and licensing laws make possible monopolies shared by large numbers of inefficient, high-cost producers. Such monopolies are no less monopolies when the more efficient, lower-cost producers who are forcibly kept out are small in number—even when there is only just *one* very large, more efficient, lower-cost producer who would otherwise gain the market that is presently monopolized.

The New York City taxicab industry provides a good example of the monopolistic protection of the inefficient many against the competition of the more efficient few.

The number of taxicabs in New York City that can cruise the streets for hire has been forcibly limited since 1937, at slightly below 12,000. Since that time, it has been a legal precondition of operating such a taxi, that one possess a small metal medallion, issued by the city government of New York and affixed to the hood of the cab. To operate a taxicab, one must not only know how to drive and be able to afford to buy a cab. One must possess a further item as well: the precious medallion, which signifies the government's permission that one can do what one already can do. If one does not possess this medallion—this fifth wheel of taxi driving, in terms of its actual physical relationship to the ability to operate a cab—one is in violation of the law and subject to arrest. In this way, the city government of New York reserves the market for taxicabs that cruise the streets, to the exclusive possession of its license holders and excludes all others by the initiation of force.

These medallions, it should be noted, now sell for a price well in excess of \$100,000 each. The price of a medallion is the measure of the additional annual income that is to be made by virtue of operating a taxicab at the higher level of rates caused by the licensing requirement and the consequent artificial scarcity of cabs. More precisely, the price of a medallion is the discounted present value of the additional income that is to be made year after year thanks to the monopoly privilege conferred by the possession of the medallion. It is equal to the principal that is necessary to make the additional annual income yield the going rate of profit and interest. If, for example, the additional annual income derived from owning a taxicab with a monopoly privilege is \$10,000, while the going rate of profit and interest is 10 percent per year, then \$100,000 appears as the value of possessing that privilege year after year. In effect, \$100,000 is the amount of capital necessary to make the \$10,000 additional income stand as a 10 percent rate of return on capital. The price of the medallion is \$100,000, because any lower price would make it possible to earn an above-average rate of profit by owning such a taxicab.

If the licensing requirement for taxicabs were abolished, more cabs would cruise the streets and their competition would drive rates down. In the face of lower rates and the elimination of the extra income presently conferred by the possession of a medallion, the pressure to reduce the costs of operating a taxicab would intensify. This would strongly favor fleet operation over individual operation. It would mean the replacement of thousands of very small, relatively inefficient cab companies, consisting of a single cab and owner-driver, by a relatively small number of much larger, more efficient taxicab companies operating substantial fleets of cabs. The fleets would enjoy such competitive advantages as the ability to keep their cabs on the road for three successive shifts a day, seven days a week; the presence of resident mechanics to minimize down-time for repairs; and the possession of spare cabs, to take the place of those out of operation for repair. Such advantages would enable them to gain vastly greater use from each cab in any given year, and not to be put out of operation—as would an owner driver—by the breakdown of any given cab.

The probable effect of fleet competition would be a decline in taxicab rates to the point where it was simply not economically possible to operate a cab as an individual owner-driver. In this way, the freedom of competition would operate, in this instance, to replace a large number of small relatively inefficient producers with a relatively small number of large, efficient producers.

It is true that it is possible to obtain the economies of fleet operation in New York City even under present circumstances, and that there presently already are some

substantial fleets. But the system of monopoly privilege eliminates the *pressure* for cost reductions and thus the adoption of the economies fleets provide. It makes it possible to operate successfully even with relatively inefficient methods. It also stops the fleets from expanding in any other way than by buying additional medalions and thus raising their price still further. In these ways, the system of monopoly privilege in the New York City taxicab industry protects the inefficient many against the competition of the more efficient few.

A similar phenomenon existed in many parts of Europe with respect to the competition of department stores and chain stores, and may still exist in some places. In order to protect large numbers of small merchants from their competition, the establishment of these stores was discouraged or simply prohibited. Here again was a case of monopoly in favor of the inefficient many against the more efficient few.

The implication of this discussion is that monopoly exists, and the freedom of competition is violated, not because there happens to be just one seller in a market, when all have the legal right to enter, but when there are millions in the market, and all *but one* are allowed to enter, with that one otherwise able and willing to enter. In such a case, the market is reserved to the exclusive possession of all but that one. It is monopolized against him. It is monopolized against him even if his entry were to result in his displacing all of the many who are in the market now and thus in his becoming the sole seller. For example, a monopoly would exist in the automobile market even if it were comprised of thousands of small automobile companies and everyone in the world were allowed to enter it with the single exception of the original Henry Ford! Such exclusion of Ford would constitute a monopoly, in violation of the freedom of competition. It would constitute a monopoly even if Ford's entry were to mean that he would then become the sole seller of automobiles, which fact would *not* constitute a monopoly.

In every case, whether a particular monopoly represents the initiation of force to protect one firm against the competition of many firms or many firms against the competition of a few firms or even just one firm, its effect is to protect the less efficient against the more efficient and to raise the price to the buyers of the good or service in comparison with the price that would exist under the freedom of competition.

Monopoly Based on Minimum-Wage and Prounion Legislation: The Exclusion of the Less Able and the Disadvantaged

Minimum-wage and prounion legislation operate to reserve labor markets to the exclusive possession of the

reduced number of workers who can be employed at the higher wage rates such legislation establishes. Minimum-wage and prounion legislation forcibly exclude from the market the additional number of workers who could be employed at the lower wage rates that the freedom of competition would establish. Such legislation also tends to reserve labor markets to the exclusive possession of *the more skilled workers*, by virtue of impairing the ability specifically of the less skilled workers to compete through the acceptance of lower wage rates. For as we saw in the last chapter, the acceptance of lower wage rates is the essential means by which those who are less skilled are able to compete with those who are more skilled.¹⁰

Minimum-wage and prounion legislation undermine the ability of the less skilled to compete with the more skilled in two ways. As in the case of the bricklayers able to lay different numbers of bricks per hour, with every forced increase in the wages of less skilled labor relative to the wages of more skilled labor, the ability of the less skilled to compete with the more skilled who are already present in the occupation is reduced.¹¹ Thus, for example, being able to accept a wage rate of five dollars an hour allows the worker who can lay only twenty bricks per hour to compete with a worker who can lay forty bricks per hour and who earns ten dollars an hour. Requiring that the worker who is capable of laying only twenty bricks per hour be paid more than five dollars an hour destroys his ability to compete.

In addition, with every forced increase in wage rates, the jobs of the less skilled become attractive to a larger number of more skilled workers, who otherwise would not have considered them. This is because standing outside of almost every occupation is a continuum of more skilled workers who could perform that occupation more efficiently than the people who presently perform it. In a free labor market, they do not attempt to perform it because the wages they receive in their present occupations are higher than those they could obtain in the less skilled occupation, even with their advantage in efficiency. But with every forced increase in the wages of the relatively less skilled occupation, such as results from minimum-wage or prounion legislation, the field is made more attractive to the more skilled workers.

Thus, for example, to the extent that a bricklayers' union could impose a minimum scale above five dollars an hour, the effect would be not only to undermine the ability of the twenty-brick-an-hour workers to compete with the more skilled, more efficient bricklayers already in the field, but to attract into the field *an additional number* of more skilled, more efficient bricklayers who presently work in other fields. For as the union raised the minimum hourly pay scale, the average cost per brick

laid would also rise, and as that happened, bricklaying would become a more attractive occupation to workers presently employed elsewhere. For example, a thirty-cent cost per brick laid would mean that a worker capable of laying forty bricks an hour could earn twelve dollars an hour as a bricklayer instead of ten dollars an hour, which is the rate corresponding to a twenty-five cent cost per brick laid. In the same way, a thirty-five cent cost per brick laid would mean that such a worker could now earn fourteen dollars an hour, and so on.

In these ways, the effect of minimum-wage and prounion legislation is not only to reduce the number employed, but to exclude specifically those who are less skilled. Thus, such legislation monopolizes labor markets specifically against this group.

It should be realized that prounion legislation has this effect even though it tends also, or even predominantly, to raise the wage rates of more skilled workers as well as those of less skilled workers. In bringing about a rise in the wages of more skilled workers, prounion legislation operates against the interests of less skilled workers in two respects. First, it operates against the interests of the less skilled or less efficient workers within whatever higher-skill category it raises wage rates. If, for example, it raises the wage rates of carpenters or plumbers, it operates to prevent the less skilled or less efficient carpenters or plumbers from being competitive through the acceptance of lower wages than the more skilled or more efficient carpenters or plumbers, for it establishes a minimum scale that is above the wage rates that are necessary for these workers to be competitive. Second, it operates to reduce wage rates and/or cause unemployment among groups of wage earners in skill categories below the ones in which it forces wage increases. This latter effect comes about because of a spillover of the workers who are displaced, into lower-skill fields.

For example, the lower-skilled carpenters or plumbers who are displaced must turn elsewhere for employment. They must turn to fields with lower skill requirements on the whole than carpentry or plumbing, such as driving a taxicab or waiting on tables. Their turning to such other fields increases the supply of labor in those fields and tends to cause a fall in wage rates in them. If the fall in wage rates in those other fields is allowed to occur, then the effect is that the less skilled carpenters and plumbers, and the other workers already in the occupations they enter, must take lower wage rates than they could have had under the freedom of competition. In other words, the monopoly legislation raises the wage rates of some workers and reduces the wage rates of others. If, however, prounion or minimum-wage legislation prevents a fall in wage rates in those other fields, then the effect is greater unemployment in those fields. And that unem-

ployment will tend to be concentrated among the least skilled people capable of performing those jobs. For the displaced carpenters and plumbers, if they are able to apply their presumably greater capacity for acquiring skill to the new occupations they turn to, will render some of those already in those fields less skilled by comparison. These others will then become the workers unemployed in those fields. And they, in turn, if they do not themselves simply join the ranks of the unemployed, will have to turn elsewhere, with a repetition of the same results on a still lower rung of skill.

In these ways, prounion legislation and minimum-wage legislation tend in the last analysis to do the most harm to the least skilled members of the economic system. At every stage, it is the less skilled against whom the labor markets are monopolized by minimum-wage and prounion legislation.

Minimum-wage and prounion legislation do not handicap exclusively the less skilled. In creating an artificial surplus of workers and the necessity of choosing among them, they also create an opportunity for the play of such factors as personal favoritism, cronyism, and racial and other forms of group prejudice. With the ability to compete by means of lower wage rates eliminated, wherever there are no discernible differences in skill among the applicants for jobs, it is such factors that tend to determine the decision of who will be employed. (And insofar as the decision of who is employed is made by labor unions rather than employers, such factors can easily outweigh differences in skill.)

Factors of this kind would not play a role in a labor market governed by the freedom of competition. In such a labor market, competition would reduce wage rates to the point where all could be employed, including those who labored under any form of social prejudice and who would be employed at a somewhat lower wage than others—to the extent necessary to offset the prejudice.

It should be realized that the freedom of competition makes it possible for people to overcome the handicap not only of a lower degree of skill, but also of such a thing as being the victims of prejudice. From an economic point of view, racial or ethnic prejudice can be taken as the equivalent of a mistaken and, indeed, irrational presumption that the members of some group are uniformly of a lower degree of skill than the members of other groups. In a free labor market, the existence of prejudice by itself—in the absence of the initiation of physical force by the government or by private groups acting with the sanction of the government—would not stop the employment of the members of the disadvantaged group. They would be employed, but, temporarily, at wage rates somewhat lower than other workers doing the same kind

of work. The discount in their wages would compensate for their presumed lack of ability.

As we saw in Chapter 6, to the extent that in fact the members of this group were as good workers as the members of other groups, any discount in their wages would serve to make their employment particularly profitable, thereby creating an incentive for their greater employment, and thereby tending to *eliminate* any discount in their wages. We also saw that the same principle would apply to the entry of the members of any group against which prejudice exists into the higher levels of employment.¹² In addition we saw that this sequence of developments cannot occur if it is stopped by the initiation of physical force, such as that practiced by bigoted local governments in the arbitrary exercise of their powers, or by organizations acting with the sanction of such governments, such as the Ku Klux Klan.¹³

In the Northern United States, racial prejudice does not appear to have been a major policy of local governments, and equal pay for equal work has long since become the rule of the market in the occupations where blacks are already accepted. Here what has held blacks back is precisely such measures of allegedly enlightened and liberal government intervention as minimum-wage and prounion legislation. This legislation works against blacks in particular not because that is the motive or intent of its authors, but because blacks, for historical reasons, are disproportionately represented in the ranks of the unskilled, and are thus disproportionately forced into the ranks of the unemployed by this legislation. Furthermore, minimum-wage and prounion legislation causes blacks not only to be unemployed, but to remain permanently low skilled. It condemns them to a lifetime of unemployment and poverty, in which they cannot gain their first job because, given their existing low level of skills resulting from such factors as lack of education, they would have to accept wages below the legally prescribed minimum. And because they cannot obtain their first job, they are prevented from raising their level of skills through experience gained on the job, and thus becoming capable of being employed later on at a wage greater than the minimum wage. As things stand, unable to develop their skills through employment, they remain permanently incapable of performing work even as valuable as the minimum wage. And so they must remain permanently unemployed.

However surprising and however paradoxical it may appear, the fact is that the whole panoply of government intervention constitutes virtual monopoly legislation against the poor and the disadvantaged.¹⁴ Precisely they are the ones whom it excludes from the market. The effect of this monopoly legislation against the poor and disadvantaged is to throw them into unemployment and keep them from

ever demonstrating their abilities in the higher levels of employment. Thus, it both perpetuates their lack of skills and maintains the existence of prejudice against them.

An important phenomenon paralleling the exclusion of the poor and the disadvantaged from the labor market by the kinds of government intervention discussed here is, of course, their exclusion from the market for medical services, as the result of government licensing requirements, which was described earlier in this section. A further major example of the harm done to the poor by government intervention is their exclusion from the housing market, and its manifestation in the growing phenomenon of homelessness. Zoning laws, government building codes, the compulsory withdrawal of land from development, laws that compel home builders to deal with labor unions and thus to suffer the artificially high wage rates and inefficiencies imposed by the unions, rising property taxes, rent control, urban renewal—all of these are ways in which the government causes either an increase in the cost of building and operating housing or a decrease in the existing supply of housing. The people who can least afford the higher costs imposed are, of course, the poor. Efforts to deal with this problem through rent control destroy the profitability of maintaining the rental housing of the poor in particular, since such housing offers the least margin for absorbing the rising costs resulting from inflation and the growing volume of government regulation. The result is that such housing is the first to be abandoned by landlords, and the poor are then left to live without running water, heat, or plumbing. At the same time, urban renewal prides itself on physically tearing down the “blighted” areas that represent much of the housing of the poor.¹⁵

Homelessness (in the cases in which the homeless are not psychotic and actually prefer to live in the streets) is a consequence of the above factors coupled with government health and safety requirements setting minimum standards for housing. In a growing number of cases, the poor are simply unable to afford housing that meets the government’s standards. The government then forcibly dispossesses them from housing that it considers substandard. At that point, they simply have nowhere to go—they are homeless. Just as in the case of medical licensing, the government’s action is analogous to passing a law—in the name of a high sounding phrase like public safety—banning all cars from the road that are more than five years old. Such a law would primarily stop poor people from being able to have a car. The minimum standards for housing do the same for housing.

Ironically, the low quality of the housing occupied by the poor is in large part the direct result of government efforts to impose minimum standards. The imposition of

these standards in any given locality and the corresponding expulsion of the poor from that locality serves to make the housing problems in surrounding localities all the worse, as a larger number of poor people are forced to compete for the diminished supply of housing that still remains open to them. Because of minimum standards imposed by various localities, poor people who might have had some kind of apartment to themselves, are forced to live elsewhere, under still worse conditions—perhaps in someone’s garage. If the housing market were free of government interference, they would not have to live in a garage, or even in the housing they are presently driven from before they get to the garage—but in housing considerably better than that and tending to get better still, with all the improvements a free economy is capable of achieving over time in housing and all other lines. Instead, however, they are driven into the streets.

Government-Owned and Government-Subsidized Enterprises as Monopoly

Government-owned and government-subsidized enterprises represent monopoly, in that markets or parts of markets are reserved to their exclusive possession by means of the initiation of physical force. Government-subsidized enterprises, of course, are a category which includes all government-owned enterprises, inasmuch as the initial resources of government-owned enterprises are provided by the government and their subsequent losses are covered by the government.

The funds of all enterprises supported by the government are obtained by means of the initiation of force against the taxpayers, who certainly do not pay taxes voluntarily for such purposes. At the same time, the subsidies make possible those enterprises’ possession of markets, or parts of markets, to which other suppliers are denied access. Competitors of the subsidized enterprises cannot gain their markets even if they are more efficient and offer better products, for the subsidized enterprises are enabled to sell their products at a loss, and even to give them away free of charge. Thus, government-subsidized enterprises are monopolies: their markets are reserved to them on a foundation of the initiation of force against the taxpayers, which then makes possible their ability to retain their markets despite the economic superiority of competitors.

The monopoly position of government-owned enterprises, and other government-subsidized enterprises, can be buttressed by the initiation of force against parties other than the taxpayers—above all, the initiation of force directly against competitors or potential competitors. The government-owned postal service in the United States is an example of this phenomenon. Here, in order to limit its losses, the government prohibits important

categories of competition, such as the delivery of first class mail, which apparently would be highly profitable to competitors at the government’s present rates. It simply declares most of the roads of the United States to be “post roads,” and then prohibits the carrying of private first-class mail over the post roads. Whoever would carry such mail would be in violation of the law, and would face the threat of fines and imprisonment.

An even more important example of monopoly than the postal service, in the category of government-owned or government-subsidized enterprises, is the public education system. The total absence of tuition charges in the public elementary and secondary schools, and the substantially lower tuition charges in the public colleges and universities, which tax-financed subsidies make possible, enable the public education system to retain the far greater share of the education market despite its clear inferiority in comparison with private schools.

As the result of the subsidies the government system receives and thus its ability to charge prices below cost—indeed, no price at all—it is not sufficient that a private school or college simply be perceptibly better in order to induce customers to give it their patronage rather than the public system. To take advantage of the superiority of the private schools, students or their parents must be prepared to pay the *full* tuition in order to gain what is merely an *improvement* on what is offered in the public system for nothing or for very little. In effect, they are placed in a position in which to choose a private school or college, they must pay the full price for what, from their perspective, is not the full product, but only a qualitative increment in the full product, because they already have the basic product from the public system for nothing or for very little.

In these conditions, before people will switch from the public schools and colleges to the private schools and colleges, they must regard the mere superiority of the private school or college as so great that it justifies paying the whole price of the education. In effect, this requires that to obtain a customer, a private school or college must be able to offer a doubled product for just one tuition. To be competitive with the subsidized school system, it must offer one part of its product, equal to what the government provides, for free. It can earn tuition revenue only on the other part of its product, which must be judged to be of such importance as to justify the payment of the whole tuition. And it must produce this doubled product at no greater cost than the tuition it is able to charge for the mere part of it—indeed, at an even lower cost, to the extent it wants to have a profit.

This is *unfair* competition. It is unjust, immoral competition. It is competition based on the initiation of force. It is not the competition of a free market, but the practice

of monopoly—the excluding of competitors by means of the initiation of force.

In the long run, public education does not, as its supporters believe, make it possible for students to obtain education who would otherwise not obtain education. On the contrary, it serves to deny education to students who would otherwise have obtained it.

In making it impossible for private schools to be commercially successful, it prevents all those improvements in quality and efficiency from coming into being that would take place in education under the competitive quest to make profits and avoid losses, and which would eventually bring a much higher quality education within the reach of all than is now available even to the wealthiest. In addition, it precludes any significant competitive barrier to deterioration in the education it itself offers.

Because it is financed by subsidies, public education has the potential to decline in quality all the way to the point where it becomes clear to most people that what it offers is no longer worth even a zero price. Only at that point does private education achieve a decisive competitive advantage in the mass market and threaten the public school system and its bureaucracy with economic extinction.

Thus, the consequence of public education is the prevention of improvements in education and, ultimately, the destruction of such education as exists. For these reasons, its ultimate effect is to deprive people of education who could have obtained it, not to promote education.

What public education accomplishes is that education is supplied without the benefit of the incentive of profit and loss in an environment of freedom of competition. If education had to operate in the same basic economic context as the automobile industry or grocery business, a powerful incentive would exist to improve quality and reduce costs. For this would be the way to increase profits. Any school or chain of schools that introduced any perceptible improvement in education would have a substantial increase in its profits. Students and their parents would want to deal with it, not its less efficient competitors: it would be giving them more for their money. Similarly, if it succeeded in cutting its costs and could operate profitably at a lower level of tuition, it would also enjoy a large expansion in business, as a larger part of the market came to prefer to deal with it, because its tuition charges were now lower than its competitors'.

In response to the competitive pressure of the loss of business to the schools which improved their quality and efficiency, all the other schools would be compelled to improve their quality and efficiency, or else be driven out of business. As the schools in this latter group caught up,

it would no longer be possible for the schools that had introduced the improvements to continue to make exceptional profits. To go on making exceptional profits, they would now have to introduce further improvements, with the same ultimate results. Thus, the basis would exist for continuous improvements in quality and efficiency, for the benefit of the buying public. All of this is simply the operation of the uniformity-of-profit principle applied to education.¹⁶

But, of course, with public education, there is no incentive of profit and loss. There is nothing to be gained within the system by introducing improvements; nor is there anything to be lost within the system in failing to match the performance of others. A loss of students, whether it results from an improvement in the performance of other schools or from a decline in the performance of one's own school, does not mean a loss out of the school superintendent's pocket or out of the pocket of anyone who sits on the local school board. At the same time, the public schools' shield of a zero or minimal tuition charge greatly reduces the volume of any additional business that any private school could obtain by virtue of improving its quality or reducing its costs within the range of what is presently feasible. As matters stand, the potential market for commercially successful private education is confined to an extremely narrow one, constituted by the children of the very well-to-do, who can afford to pay the whole price of an education for an incremental improvement.

Commercial private education is seriously hampered by the existence of costly legal requirements mandating such things as a school's provision of a cafeteria, gymnasium, library, and so forth, and limiting its ability to adopt more economical educational methods in still other respects as well—for example, requirements concerning class size, the ratio of full-time faculty to students, the minimum education of faculty, and the number of hours of in-class instruction. Its development is still further hampered by the fact that the present hostile environment fosters the tradition of noncommercial private education, in which even private education is largely subsidized—by wealthy individuals and religious organizations. In this environment, commercial private education is faced with obstacles that may simply be too great for it to overcome. It is greatly limited both in its ability to reduce costs and improve quality and in the additional market it can gain should it manage, despite all obstacles, somehow to do so. Thus, under present conditions, it is virtually impossible for it to develop the momentum of progressive improvement that would characterize it under the freedom of competition. Indeed, under present conditions, it is next to impossible for it to attract the kind of talent that would be capable of achieving major improvements in

the first place. For those who are capable of accomplishing something are not prepared to waste their time in futile efforts to move an uncomprehending bureaucracy.

The position of private education today, and that of education as a whole, is analogous to what the position of the automobile industry would be if the production of all the low- and medium-priced models were in the hands of the government, which subsidized their production to the point of giving these models away for nothing—indeed, of compelling every adult to accept one for nothing—while the privately owned portion of the automobile industry were confined to the production of very expensive models, and essentially prohibited from cutting its costs. In such circumstances, the only significant force that could operate in favor of the growth of the private automobile industry would be the total collapse in the quality of the government's automobiles. Just so, the only significant factor operating in favor of the growth of private education today is the continuous decline in the quality of public education.

In addition to public education and the postal service, government ownership of railroads, bus, and subway lines, and enterprises producing electric power, such as the Tennessee Valley Authority, represents cases of monopoly. The market of these enterprises too is reserved by the initiation of force against the taxpayers in order to provide subsidies that enable them to sell at prices below those that private competitors must charge. Government-owned roads and highways must also be placed in this category.

The Antitrust Laws as Promonopoly Legislation

However surprising it may seem, the *antitrust laws constitute promonopoly legislation*. They reserve markets to the exclusive possession of all but those who in a state of freedom of competition would occupy them. They monopolize markets precisely against the most capable and efficient firms, which, in their absence, would be able to be in those markets, and which instead, because of their existence, are today forcibly excluded from them. They prevent the capable newcomer from entering an industry—for example, they would almost certainly operate to prevent General Motors from entering the steel industry in any significant way. They prevent the capable firms within an industry from acquiring the markets of the less capable ones by absorbing them in mergers, by buying them out, or by driving them out. Ironically, while endless complaints are made about such things as high capital requirements and lack of technological knowledge as “barriers to entry,” no voices are raised to complain about the antitrust laws' forcible exclusion from markets of precisely those firms which

do have the capital and the technological knowledge required to enter them. In serving forcibly to exclude from markets precisely those firms which have the ability to enter and compete in them, the antitrust laws constitute a major violation of the freedom of entry and the freedom of competition. As such, they are among the most important instances of promonopoly legislation.

In the last analysis, what has prevented the antitrust laws from being identified as promonopoly legislation, and has allowed them to be regarded as antimonopoly legislation instead, is the irrationalist mentality underlying the anarchic concept of freedom. This irrationalist mentality places the unreal world of arbitrary desires above the real world of competence and ability. Its concept of the violation of freedom is frustration of arbitrary desires by facts of reality. It does not see as a violation of freedom the frustration of competence and ability by the initiation of physical force. Thus it holds that the existence of such things as high capital requirements are a violation of freedom of competition and a support of monopoly, but does not see as a violation of freedom of competition and a support of monopoly the forcible exclusion from markets of those who do possess the necessary capital and otherwise meet the requirements of reality. Precisely such forcible exclusion from markets is the essence of the operation of the antitrust laws.

The misguided economic rationale behind the antitrust laws will be dealt with later in this chapter.

Socialism as the Ultimate Form of Monopoly

The most extreme form of monopoly imaginable is socialism. A socialist society represents monopoly carried to its ultimate limits. The government of such a society forcibly appropriates all the means of production and thereafter forcibly reserves the entire market of its country to its own exclusive possession. Whoever attempts to compete with it is automatically held to be guilty of the crimes of misappropriating state property and of sabotaging the national economic plan, since the means of production he must use have arbitrarily been declared to be the property of the state and to be required for use in the state's national economic plan.¹⁷ Concentration camps and firing squads are held in constant readiness to deter such competitors and protect the state's monopoly.¹⁸

3. Further Implications of the Political Concept of Monopoly: High Costs Rather than High Profits

In addition to the fact that monopoly can represent the protection of the inefficient many against the competition of the more efficient few or even just one, it follows from much of the preceding discussion that monopoly

does not have any necessary connection with high profitability. There are, of course, instances of monopoly which can be associated with high profitability. Monopolies based on exclusive government franchises would be a leading case if they were not at the same time subjected to rate controls. Licensing monopolies are also cases in which profits tend to be artificially high.

But the monopolies made possible by tariff protection, government subsidies, and the antitrust laws often do not result in any exceptional profitability on the part of the monopolists. (And the monopolies based on minimum-wage and prounion legislation, of course, relate to wage income rather than profit income.) These are cases in which monopoly is established primarily for the purpose of protecting high-cost producers. The same is often true in the case of licensing monopolies as well: for example, the cases of the New York City taxicab industry and the small merchants of many European countries who obtained protection against the competition of department stores and chain stores. In many of these cases, the monopolists would be in the position of having to accept exceptionally low profits or even sustain losses in the absence of the government's help. In the case of government subsidies, they are enabled to afford to go on sustaining losses. Such monopolists turn to the government precisely because their profits would otherwise be exceptionally low or negative. Thus the high monopoly prices that result in these cases serve as much or more to cover the monopolists' high costs, due to inefficiency, as to provide an exceptionally high rate of profit. And, of course, in the case of government-subsidized enterprises, the monopoly prices charged may actually be very low or even zero.

Patents and Copyrights, Trademarks and Brandnames, Not Monopolies

Patents on new inventions, copyrights on books, drawings, musical compositions, and the like, and trademarks and brandnames, do *not* constitute monopolies. True enough, they reserve markets, or parts of markets, to the exclusive possession of the owners of the patents or copyrights, or trademarks or brandnames, and they do so by means of the use of physical force inasmuch as it is against the law to infringe on these rights.

None of these rights represent monopoly, however, because none of them is supported by the *initiation* of physical force. In all of these cases, the government stands ready to use physical force in defense of a pre-existing property right established either by an act of personal creation or by the fact of distinct identity. A new invention, or book, drawing, or song, and so forth is the product of a definite individual or group of individuals

and belongs to him or them on the same basis that a farmer's crop or a corporation's product belongs to him or it—namely, the right of having created it. A trademark or brandname belongs to its creator on the same basis as his own name—in order to distinguish the distinct identity of the individual and his actions from that of all other individuals and their actions, and thus to be able to assign individual responsibility for the good or bad that is done.

The fact that the government is ready to use force to protect patents and copyrights is fully as proper as that it stands ready to use force to protect farmers and businessmen in the ownership of their physical products and to come to their rescue when they are set upon by trespassers or attacked by robbers. In both cases, it does nothing more than protect the rights of producers to their products. In protecting trademarks and brandnames, it does nothing more than when it protects individuals from impersonation by others. It acts to enable them to be recognized for the good or bad they do, and thus to gain or lose accordingly.

The existence of patents and copyrights, and trademarks and brandnames, like all other protection of property rights, serves to increase the supply of goods and services—by making it possible for those who are the cause of the increase to benefit from the improvements they make. It thus serves to reduce prices and to increase everyone's buying power as time goes on.¹⁹

It is true that at any given time, taking for granted the existence of the most recent batch of improvements, introduced in the expectation that those responsible would benefit from them, it might be possible to achieve a temporary acceleration in the increase in the supply of goods and services by abolishing patents and copyrights. Such a temporary increase would be comparable in its ultimate significance to the abolition of the property rights of any other group of producers, such as storekeepers and manufacturers, and allowing mobs to sack their shops and warehouses. A very short-lived gain would be followed by a permanent loss of future supplies—in this case, further new inventions and new ideas. This is because no one would invest years of effort and perhaps millions of dollars of capital in the development of a new invention only to find that as soon as he brought it to market, a competitor who purchased a working model would have the benefit of all that effort and capital just for the price of the working model, and that he, the innovator, would probably be unable to profit from his efforts because of the rapid fall in the price of the product that would follow in such a situation. Ultimately, the prevalence of such conditions would cause not only the cessation of further economic progress, but also actual economic decline, as the result of the inability to offset the operation of the law of diminishing returns in mining

and agriculture, something which it is possible to do only on the basis of continuing technological progress.²⁰

The same basic principle would apply to the abolition of trademarks and brandnames, which would result in producers losing the incentive to increase or even maintain the quality of their goods, inasmuch as their goods would be rendered indistinguishable from those of everyone else, and consumers would thus have no way of singling them out for purchase. For example, imagine what conditions would be like if every soft-drink manufacturer could call his product "Coca Cola" if he wished, or if every computer manufacturer could sell his machines as made by IBM. All the efforts of Coca Cola and IBM, and of every other producer who tried to distinguish his product by its superior quality, would be wasted, because the buying public would have no way of distinguishing his product from the rest and thus no way of giving it the preference it deserved. Thus, there would no longer be any special profit in producing a superior product. The result would be that no one would attempt to produce a superior product. By the same token, no loss would attach to producing inferior products that were rendered indistinguishable, with the result that major declines in the quality of products would ensue.

Thus, contrary to monopoly, patents and copyrights, and trademarks and brandnames, operate to increase supplies and reduce prices, while their abolition would result in the opposite. Indeed, their existence must be considered *a requirement of the freedom of competition*, and their abolition as constituting the establishment of monopoly! Their existence upholds the fundamental freedom of individuals to be secure in their property and to compete on that basis. Their abolition would reserve markets to the dull and incompetent by means of the initiation of force against the intellectual property of those who had new ideas and something better to offer. Their abolition would thus serve to establish the monopoly of the dull and incompetent by forcibly depriving the intelligent and competent of the benefit of their intelligence and competence, and thereby forcibly excluding them from the market.

Because patents and copyrights protect intellectual property, their duration must necessarily be limited. It must be long enough to make it worthwhile to bring new products and new creations to the market, and yet not so long that the thinking of later generations is progressively hobbled by ever growing royalty payments to the descendants of inventors and authors. The present law of seventeen years for patent protection and the lifetime of the author plus fifty years for copyright protection seems to provide just about the proper balance between the rights of the creators of today and those of the thinking men and women and the creators of the future.²¹

All Monopoly Based on Government Intervention; Significance of Monopoly

According to the political concept of monopoly, all monopoly is based on government intervention, which restricts the freedom of entry and competition. The significance of monopoly is that it forcibly bars from the market sellers who would otherwise be capable of being in the market. It thus restricts the range of choice buyers have in suppliers and compels them to deal with less efficient suppliers and to accept higher costs and poorer quality than a free market would require them to accept.

I have shown how monopoly in the form of licensing laws is a principal cause of the growing crisis in medical care, and that to solve the crisis in medical care it is essential to assert the rational right to medical care, that is, the right to medical care from *willing providers*. This means demanding the abolition of all aspects of medical monopoly imposed by the government, which is what keeps people from willing providers of medical care.

I have shown how monopoly in the form of minimum-wage and prounion legislation operates systematically to exclude the less able and the disadvantaged from employment by depriving them of the means of competing through offering to work for lower wages. I have also shown how monopoly in the form of government-owned and government-subsidized enterprises retards economic progress and can destroy economic progress previously achieved, and that this is particularly true in the case of public education today. And, of course, I have shown how protective tariffs and antitrust legislation constitute monopoly.

On the basis of what I have shown, the program of the announced enemies of monopoly should not be, as it has been for many years, the breakup of big business or the government's growing control over big business. Rather, it should be the progressive elimination of government intervention into the economic system. This is what violates the freedom of competition and constitutes monopoly. Political progress should no longer be measured by the ever increasing hobbling of competence and ability by the threat of physical force, but by the steady disappearance of the initiation of force and thus the progressive opening up of the world to competence and ability. Such should be the profreedom, antimonopoly politics of the future. It should stand alongside of, and be an integral part of, the advocacy of economic progress and an industrial society.

4. The Economic Concept of Monopoly

In sharpest contrast to the political concept of monopoly is the economic concept of monopoly. The economic concept of monopoly holds that monopoly emerges from

the normal operation of the economic system—not on the basis of the initiation of physical force, but on the basis of mere economic circumstances, and that it nonetheless produces evils of such magnitude that the government must suppress or control it by means of force.

According to the economic concept of monopoly, monopoly exists whenever there is only one supplier of a given good in a given territory. That supplier is said to have a monopoly and to be a monopolist. The economic concept of monopoly considers the “oneness” of the seller to be the essential fact, and makes no distinction between cases in which such a seller has achieved his position by virtue of providing better goods and services at lower prices than anyone else, or has achieved it by means of physical force. No matter how he has achieved his position, it is assumed that it is a position which automatically and inherently gives him the power to inflict great evil. At the same time, the only consideration that the economic concept of monopoly gives to cases in which markets are served by more than one seller is insofar as it can construe them as somehow essentially similar to markets served by only one seller. It gives absolutely no consideration to markets in which large numbers of sellers are present all of whom are protected against the competition of more efficient outsiders. It does not consider this case to constitute monopoly in any sense.

The economic concept of monopoly can be construed in such a way that it embraces hardly anything or almost everything, depending on how broadly or how narrowly one defines a good. For example, if one considers the good “beverage,” then all suppliers of water, milk, fruit juice, coffee, tea, cocoa, and soft drinks qualify as competing producers. If one considers the narrower good “soft drink,” or the still narrower good “cola” beverage, then the number of suppliers correspondingly diminishes. Finally, if one considers the specific good “Pepsi Cola,” or “Coca Cola,” the case appears as one of monopoly, for there is ultimately just one supplier of each of those goods, namely, the Pepsi Cola Company or the Coca Cola Company. On a sufficiently narrow definition, almost everything appears as a case of monopoly.

The economic concept of monopoly has been the dominant concept for several generations. Even the classical economists held an important aspect of it, in believing that monopoly can arise in the market itself. As the classical economists used the term, monopoly applied to goods whose supply—for any reason—was incapable of further increase. Such goods—for example, wines produced on land of a special quality that exists only in a very limited extent, and paintings and statues by old masters—even though produced or sold by a substantial number of suppliers, were held to represent monopolies.

Indeed, all cases in which prices were determined by the competition of buyers for a fixed, limited supply were held to represent monopoly prices.²² Competitive prices were held to be those established by the competition of the sellers, based on the possibility of an increase in supply through additional production.²³

In the later nineteenth century and the first three decades of the twentieth century, the economic concept of monopoly in its present form was in vogue. But the concept was usually used in such a way as to imply that monopoly was a comparatively rare phenomenon—limited essentially to the cases of public utilities and local public transportation, which were thought to constitute “natural monopolies,” in the sense of offering major economic advantages by virtue of being provided by a single source. In this category were electric, gas, water, sewage, and telephone service, and subway, bus, and trolley car lines. Cases in which towns or cities happened to be served by only one railroad, or in which villages were too small to have more than a single general store, were also identified as monopolies. Apart from such cases, the rest of the economic system was assumed to be characterized by “free competition.”

In the decades between the end of the Civil War and the start of World War I, growing fears were expressed about the potential spread of monopoly to all branches of industry, coming about through the continued growth of big business, especially as exemplified in the trust movement and the waves of mergers that accompanied it. Despite these fears, monopoly was still thought to be relatively rare in actual practice, for it was unusual for any firm, however large, to have achieved a full 100 percent of the business of any given industry.

Since the 1930s, the economic concept of monopoly has come to be interpreted in ways that make almost the entire economic system fall under the heading of some form of monopoly or other. What has made possible this vast extension of the concept is the introduction of the concepts of “oligopoly” and “monopolistic competition.”

“Oligopoly” is supposedly characterized by the existence of a relatively small number of sellers in a given market. The U.S. Bureau of the Census uses so-called four-firm and eight-firm concentration ratios, according to which markets are classified as oligopolistic depending on the percentage of domestic sales of an industry made by the four or eight largest domestic firms in the industry. “Oligopoly” is held to exist in cases in which the four largest firms account for as little as 5 or 10 percent of the industry’s sales.²⁴ Depending on the circumstances, an oligopolist is held to behave either exactly as a “monopolist” would behave in terms of the price he charges and the output he produces, or to occupy some middle ground between a monopolist and a “pure

competitor.”²⁵ In the former case, oligopolists are held to be guilty of “collusion” by the mere fact of anticipating one another’s responses to changes in price.²⁶

The concept of “monopolistic competition” is supposed to describe cases in which there are a large number of sellers of only slightly dissimilar products. This concept clearly implies that an element of monopoly is present to whatever extent one product is *different* from another. The unique elements of the product constitute its “monopolistic” aspect. At the same time, such products are in competition with one another. Hence, the notion of “monopolistic competition.” According to this notion, the Pepsi Cola and Coca Cola companies are, indeed, monopolists, but, at the same time, competitors.

The concepts of “monopolistic competition” and “oligopoly” are actually indistinguishable, both in theory and in practice. As examples of “monopolistic competition,” Samuelson and Nordhaus cite the competition between Pepsi Cola and Coca Cola, Newports and Kools, and Hondas and Toyotas—examples which would equally well fit under the heading of “oligopoly,” because of the large market shares of these firms.²⁷ Indeed, even small retail establishments, such as restaurants, drug stores, and dry-cleaners—more popular examples of “monopolistic competition”—can also be classified under “oligopoly,” since there are only a few specimens of any of these categories in any given neighborhood or small town or city. Similarly, cases in which products may be physically identical, such as the cold rolled steel sheet produced by “oligopolistic” steel firms, are nonetheless likely to be accompanied by important differences in such things as terms of financing, delivery schedules, customer assistance, and so forth provided by the particular supplier.

In any case, these two concepts of “oligopoly” and “monopolistic competition” embrace virtually all industries except the few that are called “pure monopoly.” All that is now believed to remain in the realm of free competition—or “pure” or “pure and perfect competition,” as it has come to be called—is little more than wheat farming and the production of other agricultural commodities. These are the cases in which an enormous number of individually insignificant producers turn out perfectly homogeneous products and thereby satisfy the leading requirements of such “competition.” Of course, when one allows for the existence of government farm-subsidy programs and the limitations on agricultural production the government imposes, in order to limit the costs of the programs, it turns out that even most of agriculture no longer can properly be classified as falling under the head of genuine competition, but must be described as controlled by government-organized cartels.

The virtual disappearance of full-bodied competition

from the intellectual horizon of contemporary economics—a disappearance caused by the adoption of fundamentally flawed concepts—has led to efforts to reconstruct economic history, so that it can simultaneously conform both with the state of contemporary economic theory and with the generally accepted observations made in the past as to the prevalence of competition. Accordingly, the myth has grown up of the existence of a past golden age of competition before the Civil War, when, allegedly, “pure and perfect competition” was the norm. Only since then, the story goes, have we fallen from grace. This reconstruction of economic history in turn is used as a basis for explaining away much of the procapitalist economic thought of the early nineteenth century. It is claimed that the economists of that time were living in a world of pure and perfect competition and developed economic theories applicable to that world, and that, accordingly, their system of thought does not apply to the economic world that has come into being since their time.

The fact is, of course, that there never was an economic world characterized by the existence of vast numbers of sellers competing in the same market. It may be that prior to the Civil War, when each small town still had to be largely self-sufficient, because of a still undeveloped transportation network, the total number of iron foundries, meat packing establishments, and so forth, in the United States as a whole substantially exceeded the number that existed some decades after the Civil War. But this reduction in the total number of producers in many industries in the country as a whole was accompanied by a substantial increase in the number of producers in those industries *in actual competition with one another in any given market*. Improvements in transportation, in the form of railroad building and the growing use of steam-powered steel ships, made possible a radical increase in the area over which any given productive establishment was able to compete. Thus, at the same time that hundreds or even thousands of small, inefficient plants in an industry were being replaced with a much smaller number of large-scale, efficient plants, the number of firms actually competing in any given market increased rather than decreased.

It should not be necessary to say that no serious economic defense of any aspect of capitalism was ever based on the assumptions of so-called pure and perfect competition. The classical economists’ theory that prices are determined by the costs of production did not presuppose any specific minimum number of producers. It presupposed only the ability of producers to increase supplies by increasing production. Indeed, their theory of prices can be taken as regarding precisely what contemporary economics denounces as “oligopoly” and “monopolistic competition,” as the normal state of affairs, in

which both competition and the determination of price by cost take place.

Now that the meaning of the economic concept of monopoly has been explained, it is possible to turn to an analysis of the alleged significance of the concept. As will be shown, the consequences of monopoly are alleged to range from the most dire and extreme, in the earlier formulations of the doctrine, to what must be regarded as absolutely trivial, in the formulations presented by contemporary economic theory when it cries "monopoly" because of the absence of "pure and perfect competition." (It must be remarked that the triviality of the consequences of "monopoly" is not evident to the economists who support the pure-and-perfect-competition doctrine, although even they now have some awareness of the actual facts.²⁸)

5. The Alleged Tendency Toward the Formation of a Single Giant Firm Controlling the Entire Economic System: A Rebuttal

The Marxian doctrine on monopoly is that capitalism is characterized by the progressive concentration of the means of production in fewer and fewer hands. In the words of Marx himself:

Success and failure both lead here to a centralization of capital, and thus to expropriation on the most enormous scale. Expropriation extends here from the direct producers to the smaller and the medium-sized capitalists themselves. It is the point of departure for the capitalist mode of production; its accomplishment is the goal of this production. *In the last instance, it aims at the expropriation of the means of production from all individuals.* With the development of social production the means of production cease to be means of private production and products of private production, and can thereafter be only means of production in the hands of associated producers, i.e., the latter's social property, much as they are their social products. However, this expropriation appears within the capitalist system in a contradictory form, as appropriation of social property by a few²⁹

The meaning of this passage is that if left unchecked and allowed to run its full course, capitalism is headed for the day when one company and one individual or small clique of individuals will become the sole owner of the world. Ford and General Motors will merge with Toyota and Honda; General Electric, IBM, and AT&T will merge; U.S. Steel and Bethlehem will merge, as will Exxon, Mobil, and Texaco. And the combinations resulting from these mergers will combine into still larger combinations, which ultimately will sweep up all remaining independent concerns into one Supercombine that owns all the capital in the world.

This is the well-known scenario of the bigger fish swallowing the smaller fish, and in turn being swallowed by still bigger fish, until only one gigantic fish remains. This process of the growing concentration of capital is supposed to be inevitable, and is what allegedly makes the coming of socialism inevitable. The growing concentration of capital under capitalism supposedly constitutes the creation of *the structural framework of a socialist society*. Seen in this light, all that socialism represents is a mere changing of the Board of Directors of the Supercombine. Instead of the Board being composed of men who will operate the social apparatus of production in the narrow interest of a handful of dominant individuals and families, it will be composed of men of nobler character, who will operate the apparatus of production in the interest of all members of society. (To illustrate this analysis, one may imagine that on the last day of capitalism there is a board of directors of the Supercombine that is subservient to the grasping, fist-pounding General Bullmoose—the cartoon character in the old L'il Abner comic strip by Al Capp. And then, on the first day of socialism, that board is replaced by the likes of such warm-hearted and public-spirited souls as Ralph Nader, Jane Fonda, and Tom Hayden, who will proceed to run the world for the benefit of all mankind.)

Of course, argue the socialists, it is not necessary to wait for capitalism actually to run its full course. Socialism can come into being sooner, and spare the world much suffering. What is important, say the socialists, is that the coming of socialism is in accordance with inexorable principles of economic development: socialism is hatched out of the womb of capitalism, as it were.

This view of the inherent tendency of capitalist development underlies support for the antitrust laws. It is believed that the antitrust laws are necessary in order to forestall the adoption of socialism. In the eyes of their supporters, they forcibly prevent the growing concentration of capital and, at the same time, the growth of "monopolistic abuses" and dissatisfaction with capitalism.

The same view underlies all the rather sinister books and articles that periodically appear and which describe in detail alleged cabalistic schemes of wealthy individuals and families to gain control of the economic system through devices ranging from interlocking directorates of corporations to intermarriages of heirs and heiresses.

Incompatibility With the Division of Labor—Socialism as the Only Instance of Unlimited Concentration of Capital

Now any fear that there is a tendency in capitalism toward the concentration of all ownership in the hands of one man or one corporation, or any other such narrow

group, is absurd. Such a development would contradict the very nature of the gains derived from the division of labor and its corollary the division of knowledge. It would thus be against the self-interests of everyone, including even the handful of capitalists who were supposed to gain from it.

The truth is that such a state of affairs exists only under *socialism*. It is established and maintained only by the initiation of physical force. Nothing less than a Communist revolution, which forcibly seizes all the means of production and places them in the hands of the state, is capable of accomplishing it, and nothing less than the continued existence of a thoroughly repressive regime is capable of maintaining it. Despite its ownership of all the means of production in the Soviet Union, the Soviet government was able to prevent the development of competition only by means of the most repressive measures: to limit, let alone stop, the competition of the black market, it found it necessary to resort to draconic penalties, imposed by administrative tribunals, on the basis of evidence supplied by secret informers. There can be no doubt that had the Soviet government abandoned its repressive measures merely to the point of allowing its citizens to homestead unoccupied land in Siberia and produce there whatever they might be capable of producing, its monopoly position would have been completely broken. Indeed, such economic concentration as characterized the Soviet Union must be maintained not only by the resort to physical force, but also by the prevalence of a spirit of *self-sacrifice* on the part of the ruling group.

To illustrate this last point, let us imagine that in the separation between the Russian government and the Russian Communist Party, the latter had been allowed to take with it, as its own private property, all of the inhabited land of Russia and all of the factories, farms, mines, and stores that it possessed until recently in its capacity as the effective government of Russia. It would have retained title, we may assume, as the Catholic Church and the feudal lords retained title in earlier centuries to the vast properties they had originally obtained on the basis of the initiation of physical force.

If this had happened and the members of the Communist Party wished to act on behalf of their own material self-interests, or even merely to increase the wealth of the Communist Party Corporation, their first step would have been to place much or even most or all of their property into the possession of others. They would have sold out to them on credit if necessary.

They would have done so because if they consulted their own material self-interests, they would have realized how far they were from being omniscient and even how far they were from possessing the knowledge required to grow a sufficient quantity of grain to avoid

starvation. By placing a major portion or even all of their property in the ownership of others, its effective employment could be so greatly increased, so much more could be produced, that the Communist Party as a private corporation would soon have found itself materially much better off owning 20 or 25 percent of a greatly expanded Russian economy than 100 percent of the then existing Russian economy. And as time wore on, its relative significance in the Russian economy would have continued to decrease, though its absolute wealth might have continued to increase.

None of this is to advocate in the least that Russia should have been or should be desocialized in this manner. The Communist Party and its members have no right to anything. It is merely to make the point that anyone truly following his self-interest knows that it is to his self-interest that there exist other people able to act and produce without being dependent on the use of his property and thus on obtaining his consent—that is, that there exist other people capable of acting and producing without being limited by the limits of his knowledge. (Along these lines, of course, an essential advantage resulting from the end of socialism is the reestablishment of markets for all goods and services and thus of the price system, economic calculation, and economic planning—vital features which socialism lacks.³⁰)

Indeed, although it has taken a different form, what is going on today in the former Soviet Union and throughout the Communist and formerly Communist worlds is precisely the growing realization that an all-embracing economic monolith is not in the interests even of those who are in charge of it. The great mass of present and former members of the Communist Parties around the world, extending high up into the ranks of the various central committees, will all be far more prosperous under capitalism than under socialism, even though they have been the ones in charge of the monolith. Finally, they appear to have come to understand this fact, and for some time have been seeking ways to dismantle socialism and establish capitalism, and to varying degrees are succeeding in doing so.

The entire experience of socialism confirms the fact that monopoly is a political phenomenon, not an economic phenomenon.

Inherent Limits to the Concentration of Capital Under Capitalism

In order to show further why there is no tendency toward an ever increasing concentration of capital under capitalism, it is necessary first of all to elaborate on the fact that beyond a point concentration of capital runs counter to the division of knowledge.

No businessman or team of businessmen is capable of

possessing the knowledge required to succeed in more than a few industries. There is simply too much to know. For this reason, there is the phenomenon of *bad mergers*—acquisitions that do not fit into a company's areas of expertise and which thus turn out to reduce profits rather than add to them. Such ill-fated acquisitions must later be “spun off”—divested—if they are not to constitute a continuing drain on the profits of the company's sound operations.

It is not possible—in the absence of government intervention that seriously undermines normal profit-and-loss incentives—to overcome this problem through the formation of conglomerates, with separate divisions each under the control of businessmen with the necessary knowledge of the particular area of specialization. A businessman with confidence in his own ability to succeed in an industry he knows and understands, and in which his income is determined exclusively by his own success or failure, would not be willing to exchange such a position for one in which he receives a much smaller share of the profits of a conglomerate, which are the outcome of the success or failure of many others, whom he is unlikely to consider as capable as himself.

Similar considerations operate to frustrate the combination of firms even within the same industry. Imagine, for example, an industry composed of 10 firms, each presently doing 10 percent of the industry's business, and owned by individuals each of whom expects that under his management his firm will grow to the point of doing 40 percent or 50 percent of the industry's business. It is not possible to merge such firms. To make the merger appear worthwhile in comparison with the anticipated gains from remaining independent, each of the 10 would have to be given 40 percent or 50 percent of the stock of the resulting combination—or 4 or 5 times the value of the combination in all.

It is not necessary, of course, that all of the firms in an industry hold such an optimistic view of their prospects. So long as there are *any* firms who believe they will enjoy a substantial increase in the share of the industry's business they will do if they remain on their own, it is probably not possible to offer them terms that would make merging appear worthwhile.

Furthermore, it should be realized that when mergers take place that are *successful*—that is, succeed in realizing important economies—a major consequence is the formation of new and additional capital. The stockholders in such a combined enterprise enjoy higher incomes, can save more, and the value of their shares of stock is increased. The result is that these stockholders are now in a position to finance the launching of new firms—not, most likely, in the same industry in which the merger has occurred that underlies the increase in their wealth, but

in other industries. Yet if successful mergers take place throughout the economic system, a consequence will be the formation of new firms throughout the economic system, and thus in most or even all of the industries which have experienced mergers. In effect, successful mergers in the oil, steel, and cement industries, say, result in the formation of additional capital which makes possible the launching of new firms in, say, the automobile, aluminum, and chemical industries. Later on, successful mergers in one or more of these industries, or in other industries, result in the formation of additional capital that makes possible the launching of new firms back in the oil, steel, and cement industries.³¹ Thus, the very process of successful mergers is itself the source of the formation of new firms and thereby operates to limit the concentration of capital.

In addition, it should be realized that an enormous number of new small firms is started every year in a capitalist economy with or without the aid of capital generated by the process of successful mergers. Over the years, some of these firms enjoy great success and grow into medium and even giant-sized firms. One has only to think of the present-day American computer industry or the present-day Japanese and Korean automobile and steel industries. The continuous formation and success of new companies makes it possible for mergers to go on as a regular phenomenon, without being accompanied by any actual increase in the overall degree of concentration of capital in the economic system. While the merged firms represent more capital in the hands of fewer firms, the growth of new firms represents more capital outside the hands of the merged firms. Thus, the proportion of the total capital of the economic system in the hands of the merged firms does not grow.³²

Government Intervention as Limiting the Formation of New Firms

It must be pointed out that the formation and growth of new firms would take place on a much greater scale than at present precisely under conditions of *laissez-faire* capitalism. A major potential source of the formation of new firms in virtually every industry is key executives of the existing firms who believe that they could do better on their own. If not for the personal income tax, such executives would be able to accumulate far more personal wealth in their present positions. In the absence of restrictions on stock trading based on “inside” knowledge, their accumulations of personal wealth would be greater still.³³ In such conditions, it would be possible to start even new domestic automobile and steel companies requiring an initial investment of a billion dollars or more. A group of a half-dozen or a dozen key executives of existing automobile or steel firms might well have a

collective personal net worth of several hundred million dollars. On the basis of that equity, combined with their knowledge and experience, they would be in a position to raise any necessary additional capital from outside sources, such as banks or a public stock offering. This potential competition, of course, is aborted by the government intervention—most notably, the progressive personal income tax—which prevents the accumulation of the necessary personal wealth by these individuals. And then, of course, the very same people who advocate such government intervention denounce capitalism for the fact that no one has the capital to start such new firms!

Taxes and other government regulations undermine the formation and growth of new firms also by virtue of the amount of time and effort they require firms to devote to the paperwork and other regulatory procedures that are imposed. Small firms just starting out simply cannot afford the staffs of accountants, lawyers, lobbyists, and others that are necessary to cope with the burden of government regulation. The established, large firms are in a much better position to do so. Here again are important instances of promonopoly policy, this time, on behalf of the established, large firms.

The Incentives for Uneconomic Mergers Provided by the Tax System

Besides preventing the formation and growth of new firms, the tax laws have also encouraged mergers that lack a genuine economic basis. Until 1981, firms that had been profitable in their existing lines of business were given an incentive to branch out into different lines of business in which they did not possess any special competency, as a means of reducing the tax burden of their major shareholders. Paying out the profits from their existing lines of business in the form of dividends would have imposed a federal income tax rate of 50 percent on stockholders in the top bracket. On the other hand, using those profits to buy the assets of another firm served to increase the company's assets and the price of its common stock. Upon selling their stock at a higher price (provided it had been held for a year or longer), stockholders had only to pay the capital gains tax of 20 percent. Such an arrangement, which had prevailed for many years, obviously favored giving stockholders their profits in the form of capital gains rather than dividends, and, as a means of accomplishing this, the use of profits for acquisitions which otherwise would not have been made.

By the same token, such considerations provided an incentive to the owners of successful small and medium-sized concerns to sell out to larger firms rather than continue on and attempt to grow further on their own. To enjoy the fruits of their success by paying themselves

large dividends, they would have had to pay the 50 percent federal income tax. But by selling their shares, either for cash or in exchange for shares in the acquiring company, they could obtain capital-gains treatment on whatever portion of their firm's profits they wished to enjoy.

And, of course, the tax laws provide an incentive for acquiring firms which have accumulated losses over the years. When such a firm is acquired, its losses are subtracted from the profits of the acquiring firm, and thus the corporate income tax that must be paid by the acquiring firm is correspondingly reduced.

The preceding remarks are not intended in any way to provide an argument for raising the capital gains tax or for restricting the ability of businesses to reduce their shareholders' tax burden through mergers or through buying firms that have accumulated losses. Anything which serves to reduce the taxes paid by business firms and their stockholders serves to increase substantially the supply of capital funds available and thus to promote capital accumulation and economic progress. The achievement both of this vital end and of the elimination of the incentive to uneconomic mergers would be served if income tax rates were reduced below the capital gains tax rate. The incentive to acquire loss-making concerns merely for tax purposes would be eliminated entirely, and the incentive and means for accumulating capital would be increased enormously, if the whole system of income taxation were simply abolished.

In Defense of "Insider Trading"

In connection with market processes limiting the concentration of capital, I have made favorable reference to stock trading by corporate executives based on their inside knowledge. Inasmuch as a great deal of scandal has become attached to the phenomenon of "insider trading"—as though it represented some sort of heinous crime—it is necessary to say something further, in defense of the phenomenon.

There is absolutely nothing wrong with insider trading, even in situations in which corporate executives might sell the stock of their own company short (provided, of course, that they did nothing to cause the negative developments that could be expected to reduce the price of their company's stock). Insider trading does not make the "insiders" rich at the expense of any shareholder who continues to hold his shares. If the insiders profit by buying in advance on their inside knowledge of favorable developments, the effect is simply that the stock price starts to rise sooner. Whoever has decided to hold the stock gains that much sooner. Some who were planning to sell the stock, upon seeing the rise caused by

the insiders' buying, may be persuaded to hold it instead; people in this group enjoy gains they would otherwise not have had. Whoever had made up his mind to sell his shares is enabled to sell them at a better price, thanks to the demand for them coming from the insiders.

The only parties who have any possible basis for complaint are those who do not have any strong conviction about the company's future prospects and who are induced to sell at the higher price the insiders bring about, and those who were planning to buy and who must now do so at a higher price. The complaint of people in the first group is that they accepted what they thought was a good price at the time and somehow have a right to the same gains they would have had if they had known better or had had more confidence in the company's future. The demand that the insiders must work for the "stockholders" actually means that those who see the value of becoming stockholders, or of increasing their holdings, must work for the benefit of those who do not see the value of continuing to be stockholders. It is a demand that they work for the least committed, least loyal of the stockholders, who upon the first opportunity cease to be stockholders and who are no longer stockholders when the inside news finally becomes public knowledge. There is no good reason why the interests of the insiders should be sacrificed to the interests of such people. As for the buyers who pay a higher price, their only complaint can be that their gain is less than it might have been. But many of them may well be buyers in the first place only because they observe the rise in the stock price brought about by the insiders' buying.

If the insiders sell in advance on the basis of their inside knowledge of negative developments, they are not responsible for the loss that is suffered by those who continue to hold the stock. That loss would come in any case, when the bad news finally became public knowledge. Only it would come more precipitously and dramatically, rather than being preceded by declines caused by the insiders' selling. As matters stand, the insiders' selling and the lower price it causes provides a clue to other stockholders to begin selling and to potential buyers to abstain from buying. Those who decide to buy in any case, are enabled to buy at a lower price.

The opposition to insider trading is actually based on nothing more than malicious envy—envy of those who profit by knowing what they are doing, by those who lack knowledge and who demand profit nonetheless. Ironically, their claims are upheld with righteous indignation by the very people who regard all stock market activity as pure gambling and all the gains made in the stock market as unearned and undeserved. Indeed, if the gains of the insiders, who know what they are doing, must be transferred to those who do not, the latter will not be able

to keep those gains for very long. For they will have no basis on which to argue for the retention of their unearned, accidental gains from society as a whole. If knowledge is not an adequate basis for earning a profit that others do not earn, the mere accident of owning the right stock at the right time can hardly be such a basis. The attacks on insider trading proceed from a fundamentally anticapitalistic perspective. Their purpose is not to benefit any alleged group of victims, but to defame and ultimately destroy capitalism.

6. Economically Sound Mergers

Despite the fact that government intervention today encourages many economically unsound mergers, conditions often exist in which mergers are economically sound. By making possible an increase in the scale of a company's operations, they often achieve important economies of the kind previously described in the discussion of the gains from the division of labor, and which, appropriately, are termed economies of scale.³⁴ For example, by virtue of concentrating a larger quantity of work of the same type in the same place, they make it possible for smaller individual steps in the production of a product to come to have to be performed with such frequency that they can constitute the full time jobs of workers. For example, 100 automobile companies each turning out 10 automobiles a day, cannot make full-time, eight-hour-a-day jobs out of individual steps in producing an automobile that require less than 48 minutes of labor time. But a single automobile company, turning out 1,000 automobiles a day in the same factory, can make full time jobs out of individual steps requiring as little as .48 minutes of labor time. This represents the establishment of a substantially higher degree of division of labor and achieves important economies of learning and motion.

Similarly, larger-scale production frequently makes it possible to adopt machine methods which would be uneconomic on a smaller scale of production. For example, it probably does not pay for two companies to install machines of the kind that they will each use only 40 percent of the time. Still less would it be likely to pay four companies to install machines of the kind that they would each use only 20 percent of the time. But one company, producing twice or four times the volume would use such machines 80 percent of the time, at a correspondingly lower unit cost of the machine's services. Thus the adoption of machine methods is favored by a larger scale of operations.

Mergers can achieve important economies in cases in which companies carry complementary product lines, which can easily be sold by the same sales force. For

example, if many of the customers of steel companies frequently need both steel sheet and iron castings, it is probably more economical for both products to be provided by one company than for each of two companies to provide only one of the products.

Mergers can also achieve important economies in connection with advertising and the raising of capital. For example, newspaper and television advertising are more economical if what is advertised is available throughout the area reached by the advertising. On this basis, it pays chain stores to engage in advertising which would not pay neighborhood shops. Larger firms, resulting from mergers, are also able to carry on their financing on a larger scale. As a result, other things being equal, they can borrow money at lower interest rates, since the lender can spread the administrative costs of making the loan over the larger sum lent. Similarly, sufficiently large firms, with sufficiently large financial requirements, can justify listing on a stock exchange and thus obtain the more economical access to capital that that makes possible.

Perhaps the single most important gain achieved by mergers is the ability of more competent individuals to gain control over the management of additional capital. If there are two firms each with the same capital, but one is run by more competent people than the other, the extension of the management of the former to the assets of the latter, will result in the combined firm producing more than was produced by the two individual firms separately. Even apart from economies of scale, two railroads merged under the management of Vanderbilt, or two oil refineries merged under the management of Rockefeller, resulted in more than twice the respective production of the two outfits in isolation, simply because the acquired assets were managed better in the hands of their new owner. It should be obvious from this point in particular that the economies provided by mergers can go far beyond the economies of scale achieved in individual larger-sized factories or other productive establishments. There is very good reason for a more competently run firm to own far more than just one optimum-sized plant in its industry. Its ownership of additional such plants results in more being produced from them than would be the case if they were owned by less competently run firms. It is necessary to stress this point in view of the widespread belief that economies of scale provide the only economic justification of mergers.³⁵

The Trust Movement

The preceding discussion helps to explain an important part of the economic history of the late nineteenth and early twentieth centuries—the phenomenon of the so-called trust movement. The trusts were the earliest method devised for accomplishing corporate mergers.

Prior to the Civil War, the formation of corporations was an extremely difficult and costly process. A special act of a state legislature was necessary. Corporations were confined largely to railroading and insurance. In the years following the Civil War, with recognition of the growing need for large aggregations of capital, requiring the participation of such a large number of investors as to make traditional partnership arrangements unwieldy and impractical, the process of incorporation was radically simplified and the ability to incorporate was made easily available to everyone.

In the period following the Civil War, corporate law did not immediately provide a mechanism whereby one corporation could be combined with another one. The trusts were a device for accomplishing that purpose. Under a trust arrangement, the stockholders of separate corporations turned their shares over to trustees, who then had the power to vote the shares and run the corporations. By assembling the shares of two or more corporations in the hands of the same trust, it was possible to operate the corporations as a single unit and thus achieve a merger.

Despite the sinister connotations of the word, the trusts played a major role in improving the efficiency of the economic system, and thus in raising the general standard of living. Their success in rapidly increasing production was instrumental in bringing about a generation of steadily falling prices in the years 1873–1896. (The fall in prices came to an end with major discoveries of gold in Alaska and Australia, and the development of processes which made possible the commercial exploitation of a vastly increased portion of South Africa's deposits.) In every case, the rise of the trusts was associated with a vast increase in production and improvement in the quality of products. The era of the trusts was the era of America's most rapid economic progress and the transformation of the country into the world's foremost industrial producer and economic power. The development of the trusts was indispensable to these achievements.

The fact that the actual result of the trusts was more production and lower prices, not less production and higher prices, which is the result one would expect if the trusts had been the monopolists their critics claim them to have been, is confirmed even in the adverse decision of the U.S. Supreme Court in 1911, which broke up the Standard Oil Trust. In its decision, the Court admitted: "Much has been said in favor of the objects of the Standard Oil Trust, and what it has accomplished. It may be true that it has improved the quality and cheapened the costs of petroleum and its products to the consumer. But such is not one of the usual or general results of a monopoly; and it is the policy of the law to regard, not

what may, but what usually happens. Experience shows that it is not wise to trust human cupidity where it has the opportunity to aggrandize itself at the expense of others."³⁶ Ironically, of course, the leading "evidence" that is usually cited on behalf of the terrible effects of the trusts and of private "monopoly" in general is precisely the alleged record of the Standard Oil Trust!

Apart from the special business talent that was characteristic of the men who formed the trusts, and the advantages to be had by virtue of that talent being in charge of a larger volume of capital, a fundamental economic factor that favored the formation of the trusts—indeed, made their formation vital—was the major improvements in the transportation system that had been going on for several decades, and which sharply accelerated following the Civil War. The decades following the Civil War were a period of enormous railroad building, and also of the rapidly growing use of steam-powered steel ships. These developments brought about a radical reduction in transportation costs and the ability to transport quickly and economically, to practically everywhere in the country and to much of the world, goods whose transportation prior to that time had been extremely expensive and for all practical purposes simply out of the question as far as most locations were concerned.

These improvements in transportation favored larger-scale manufacturing and processing. They meant that the lower manufacturing and processing costs of larger-scale plants would outweigh transportation charges over a wider radius, and thus that the adoption of larger-scale manufacturing and processing methods was now economic in a vast number of situations in which it had not previously been economic. The following hypothetical example will serve as an illustration.

Imagine that in a small-scale plant, manufacturing cost is \$10 per unit of product, while in a large-scale plant, thanks to the operation of the kind of factors explained above, manufacturing cost can be brought down to only \$1 per unit, provided the facility operates at a sufficient percentage of its capacity. Assume that initially, however, transportation costs are 50¢ per mile per unit. Under these conditions, transportation charges more than offset the manufacturing cost advantage of the larger-scale plant in every case in which it is located more than 18 miles further away from the market it must serve than is the smaller-scale plant. The total cost per unit of providing the product from a smaller-scale plant located on the spot, and thus without its having to incur transportation charges, is \$10 per unit—its manufacturing cost. But that is exactly the total cost of providing the product from a larger-scale plant located only 18 miles away, when one adds to its \$1 manufacturing cost per unit,

transportation charges of 50¢ per mile times 18 miles. Indeed, in every case in which the larger-scale plant is located more than 18 miles further away from the market than is the smaller-scale plant, the closer, smaller-scale plant actually has the cost advantage. The smaller-scale plant located, say, 5 miles from the market it must serve, has a total, delivered cost of \$12.50 per unit. The larger-scale plant located, say, 30 miles from that same market has a total, delivered cost of \$16 per unit.

In such circumstances, it is doubtful that the larger-scale plant can compete successfully against smaller-scale plants even when it is located in the same immediate vicinity. This is because it must find the volume of business necessary to enable it to operate at a sufficient level of its capacity within too small a radius. It may well be the case that when confined to such a narrow radius, the volume of business it can attract is so small that at the low level of operation it is able to achieve, even its manufacturing cost turns out to be no lower than that of the smaller-scale plant. Indeed, a larger-scale plant that must operate at, say, only 5 or 10 percent of its capacity, may well have higher manufacturing costs than a smaller-scale plant operating at 80 or 90 percent of its capacity.

Such results are not unlikely. Any inability to find a sufficient volume of business within the narrow radius enjoined by the high transportation charges diminishes the manufacturing-cost advantage of the larger-scale plant and forces it to find its market still closer to its gates, which then compounds the problem of finding a sufficient volume of business. For example, if the larger-scale plant could find sufficient business within an 18-mile radius to operate at no more than 25 percent of capacity, even though it charged prices corresponding to manufacturing costs at an 80 percent or 90 percent operating rate, its manufacturing cost per unit would be substantially greater than \$1—perhaps \$4. In that case, to operate economically, it would actually have to find a sufficient volume of business to support 25 percent operation within a radius of 12 miles, not 18 miles, for its actual manufacturing cost advantage over the smaller-scale plant is reduced to \$6 per unit from \$9 per unit. If it cannot do that, then the same story repeats itself, and it is driven to having to find an adequate market even closer to its gates, at a still lower percentage of capacity, and at correspondingly higher manufacturing costs per unit. The probable outcome is that it cannot operate economically at all.

But now imagine that, thanks to radical improvements in railroading and ocean shipping, transportation cost is reduced to a mere 1¢ per mile per unit. Under these new conditions, the larger-scale plant has an advantage in total, delivered cost per unit extending over a radius of 900 miles! Wherever its distance from the local market is less than 900 miles further away than the small-scale

plant, it has the lower total delivered cost. In these circumstances, the larger-scale plant will almost certainly find a sufficient volume of business so that it can operate at a level of capacity high enough to achieve its manufacturing economies. Indeed, probably at least several such plants will be required.

The much maligned trusts were precisely the means of achieving the replacement of high-cost, small-scale plants with much lower-cost, large-scale plants. They accomplished this by merging large numbers of small firms, with small-scale facilities, into a smaller number of larger firms, with large-scale facilities. They built the larger-scale facilities by pooling the profits and replacement funds of the smaller concerns, and as they built them, they dismantled and closed down the outmoded small-scale facilities. For example, Standard Oil is reported to have acquired 123 refineries, of which it dismantled at least 75, while producing a greatly increased volume of oil products in only 20 separate facilities.³⁷ In accomplishing such results, the trusts brought into being large-scale manufacturing and processing centers serving national and world markets at radically reduced costs and prices. For example, they developed Cleveland as the major oil-refining center, Pittsburgh as the major steel-producing center, and Chicago as the major meat-packing center.

The historical distortions surrounding the trusts totally ignore their actual accomplishments and substitute for the facts nothing more than the implications of moral and economic doctrines that are themselves totally unfounded—above all, the implications of the vicious doctrine that one man's gain is another man's loss. On the basis of this depraved doctrine, the trusts are damned *a priori*, precisely by virtue of their great success.

7. The Predatory-Pricing Doctrine

An economic doctrine that has played a major role in the condemnation of the trusts and in the fear of big business in general is the doctrine of predatory pricing. According to this doctrine, a large firm, because it is "big and rich," and possibly operates in many different markets at the same time, can afford losses which a small firm cannot, because the latter is "small and poor." On this basis, it is held to be in the interest of the large firm temporarily to slash its price and sell at a loss, in order to force the small firm also to sell at a loss. Because it can afford the loss while the small firm cannot, the argument goes, it will be able to drive the latter out of business, and, as soon as it has done so, raise its price to a higher level than ever before. New competitors will be kept out, the doctrine claims, by the fear of being ruined by a repetition of predatory price cutting. Thus, it is held,

the predatory large firm succeeds in unconscionably gouging the helpless public, which, in simple innocence, has taken the large firm's lure of a temporarily lower price as children sometimes take candy from an evil stranger, only to suffer greatly later on from its mistake, when its only protection, the small and poor firm, has been eliminated.

The belief in the validity of this doctrine is so powerful that all the achievements of big business in reducing prices and improving quality are regarded as having no reality. They are all seen as being merely a prelude to this kind of gouge. Conditions will be normal, the doctrine's adherents believe, only when big business and the rich do what it is absolutely certain that their nature impels them to do and, indeed, makes them enjoy doing, namely, make life miserable for everyone else.

Despite the evident psychological bias that underlies its acceptance—namely, envy carried to the point of unreasoning fear and hatred of others' success—it is necessary to examine the predatory-pricing doctrine as though it were advanced in all good faith and honesty. Proceeding in this way, a series of major difficulties with the doctrine must be pointed out.

First, it should not at all be taken for granted that the large, rich firm is even in a position to impose a price reduction below the small firm's costs. At the lower price it asks, there will be an increase in the quantity of the good demanded. The large firm can make the lower price effective only if it is in a position to supply this additional quantity demanded. Whether or not it can do so depends on how elastic the demand for the product is in response to the price reduction—i.e., on how much the quantity of the product demanded expands—and also on how much unused productive capacity the firm has on hand and that is available for the particular market concerned. If its capacity is insufficient to meet the larger quantity demanded, it has no means of compelling its small competitor to sell at the lower price it asks. For in this case, customers who come to it in order to obtain the lower price must be turned away. They will have to deal with the smaller firm. Indeed, it is even possible that the effect of the large firm's action could actually be to *raise the price received by its small competitor*. This will occur insofar as its lower price attracts a new and additional quantity demanded which is met with supplies that are now made unavailable for satisfying the firm's regular quantity demanded. In this case, the item actually becomes scarcer for the firm's regular customers, and they will now have to turn to the smaller firm, where their competition will actually drive up the price.³⁸

If the large firm does have the capacity to meet the additional quantity demanded at the lower price, and thus to satisfy a substantial portion of the customers of the

smaller firm as well as all of its own customers, then, of course, it can impose the lower price. The smaller firm will have to meet it if it wishes to keep its customers.

But even so, to the degree that the demand for the product is elastic, the large firm must go to the expense of possessing this necessary additional capacity. And then, of course, if it should actually succeed in closing down the small competitor and thereupon raise its price, which is its presumed plan all along, it must continue to maintain this additional capacity even though it no longer uses it in production. This can be an expensive proposition.

A further, much greater difficulty arises. If it is the case that as soon as the small competitor is driven out, the large firm can sharply increase its price, while so long as the small competitor remains in business the price is held below the level of his costs, then usually unrecognized but nonetheless extremely powerful interests are created on behalf of the continued existence of the small competitor. The obvious interests, of course, are those of the small competitor himself, who wants to stay in business, and those of the industry's customers, who pay much less so long as he is in business, and so much more as soon as he is driven out of business. A less obvious interest in the continued existence of the small competitor is that of *the industry's suppliers* and that of *the producers of products that are complementary to the industry's products*.

If, for example, a predatory-pricing policy were to be followed in the oil industry (as many believe was actually the case in the late nineteenth century and the early years of the twentieth century under Rockefeller's Standard Oil Company), the consequence would be that the business of the suppliers of oil rigs, drills, pipeline, and tank cars would sharply increase every time a small competitor existed who was being driven out by Standard Oil, and sharply decrease every time Standard Oil succeeded in driving him out. The same would be true of the business of the automobile industry and its suppliers, which is increased by a low price of gasoline and reduced by a high price of gasoline. The obvious question arises, if Standard Oil were to follow such a policy, why shouldn't the suppliers of the oil industry and the producers of products complementary to oil products, like automobiles and steel, deliberately subsidize a small competitor of Standard Oil, for the very purpose of making Standard Oil sell at a sharply lower price?

Going still further, if it is the case that the large firm has only to be confronted with a small firm in order to slash its price, people are placed in a position in which they can use that very knowledge to profit by forming small competing firms. All they have to do is first go out and take a substantial short position in the stock of the

large firm, and in the product it sells. They can do so in the knowledge that they have the power to drive down the price of its stock along with the price of its product while it proceeds against their new company by means of slashing the product's selling price and its own profits. And as a kind of frosting on the cake, as it were, as soon as they have taken their short positions, they can publicly advertise the formation of their new company and urge everyone to delay his purchases of the product in anticipation of the sharply lower prices their entry will precipitate. This will immediately reduce the business of the large firm, enable the owners of the new firm to profit right away on their short positions, and when their firm actually appears in the market, the quantity of the product demanded may be so increased, thanks to the postponement of purchases, that the large firm may not even be able to meet it. The result of this last is that for a time the small firm may even be able to sell at prices that are highly profitable despite all the efforts of the large firm.

Of course, apart from all of these considerations, there is the very simple and obvious question of why all the customers are ready to deal with the large firm if they know that as soon as it succeeds in driving the small firm out, it will sharply increase its price. In reality, buyers take steps to protect themselves from arbitrary price increases. In addition to the simple refusal to give all their business to such a firm, a further major protection is *prices that are set by contractual agreement*. Such prices can altogether eliminate the ability even of firms that constitute the sole source of supply to profit from arbitrary price increases. I will say more about this shortly.

There is yet a further and particularly vital matter that the predatory-pricing doctrine ignores and which must now be pointed out. This is the fact that to the extent that the big and rich firm is larger in the same market, it must take the price cut and the resulting loss *on a correspondingly larger volume than the small and poor firm*. It cannot cut the price only to the customers of the small firm, because that leaves the small firm free to cut price by a much smaller amount to an equal number of customers of the large firm. If the small firm is not to be able to sell to anyone except at the low price imposed by the large firm, the large firm must make that low price available to all of its own customers as well as to the customers of the small firm. This means that if—to introduce an element of personality into the example—"Big John" (viz., Rockefeller), who does 90 percent of the business in a given market, wants to cut price in order to inflict a loss on "Little Joe," who does 10 percent of the business in that market, he must suffer the resulting loss on his *90 percent* share in contrast with the latter's 10 percent share. Assuming that he has the same unit costs, this means nothing less than that he must take a

loss that is *nine times as large!* It is difficult to see the advantage constituted by nine times the wealth and nine times the business if money is lost at a rate that is nine times as great.³⁹

Indeed, when matters are seen in this light, it even turns out that the smaller, poorer firm may be in a better position to withstand losses than the larger, richer firm. If, for example, while Little Joe's market share was only one-ninth as great as that of Big John, his capital was more than one-ninth as great—say, two-ninths as great—then he would actually be in a position to sustain losses for a longer time than Big John! And if Little Joe is an innovator and produces a superior product at the same cost as Big John's product, or has lower units costs of production than Big John for an equally good product, then his position is virtually impregnable. In this case, by cutting price Big John can suffer immense losses, while Little Joe merely earns lower profits, and Big John must suffer even greater losses before he can impose any loss whatever on Little Joe. (Such a situation is very often the case in reality, though it is hardly ever considered by the supporters of the predatory-pricing doctrine or, for that matter, by almost anyone else in contemporary economic theory.)

Of course, Big John's larger capital can often be expected to give him economies of scale which Little Joe does not possess. In recognition of this fact, the predatory-pricing doctrine's supporters may wish to modify their position that it is greater wealth and size in and of itself that enables the larger firm to sell at lower prices. They may wish to say that Big John can afford to sell at lower prices because he has lower costs, which permit him to continue to be profitable even while Little Joe earns no profits, or, indeed, suffers losses. There is certainly nothing objectionable in Big John selling at lower prices in such a case. But even here, it should be realized that in selling at lower prices, the more efficient, larger firm must still at least *reduce* its own profits by a multiple of any loss it inflicts on its small competitor, which makes it extremely unlikely that it could pay to cut prices for the purpose of driving the small competitor out.

For example, let us imagine that Big John has a cost per unit of 80¢, while Little Joe has a cost per unit of 90¢ and needs a price of \$1 per unit in order to earn a competitive rate of profit on his capital. If Big John sets his price at \$1 per unit, and sells 9 units for every 1 that Little Joe sells, then he makes \$1.80 in profit for every 10¢ that Little Joe makes. If now, he slashes his price below Little Joe's cost, to 85¢, say, then for every 5¢ of loss he inflicts on Little Joe, he reduces his own profits by 15¢ per unit times 9 times the number of units, viz., by \$1.35. The damage he does himself in this case, in terms of the reduction in his own profit, is 27 times the loss he inflicts on Little Joe. To describe the situation in

more conservative terms, the reduction in his own profit is still 9 times the reduction in Little Joe's profit, which goes from plus 10¢ to minus 5¢. But however it is described, this hardly seems to qualify as an intelligent method of doing business. On the contrary, it seems to have more in common with a policy not merely of shooting flies with an elephant gun, but of perversely singling out for such shooting, flies that reside on one's own nose! From the perspective of the smaller firms in competition with such absurdly managed large firms, it would simply be a case of "the bigger they come, the harder they fall."

Furthermore, in order to drive Little Joe out of competition, or, more correctly, Little Joe's plant capacity, Big John must sell not merely below the latter's total costs, but below his *operating costs* (together with an allowance for earning a competitive rate of profit on the working capital that must be tied up in meeting the operating costs). Little Joe's operating costs are his costs merely on account of such things as labor, materials, and fuel. Such costs as depreciation on plant and equipment and interest paid on capital borrowed for investment in plant and equipment do not enter. So long as Little Joe, or whoever else may come to own Little Joe's plant, can sell merely for more than these costs plus an allowance for earning a competitive rate of profit on the working capital that must be tied up in meeting them, it pays him to remain in operation. To whatever extent Big John charges a price that is higher than this, Little Joe or his successor is also able to recover a portion of the original investment in the plant and equipment.

To drive out Little Joe, Big John must not only set his price below this level, but he must also hold it at this low level *for as long as Little Joe's plant capacity lasts*. Even if Little Joe himself should be driven out of business, because he is unable to meet interest or principal payments, say, continued operation of his capacity will pay the creditors who take over his assets, or those to whom the creditors sell the assets. This is the case, because, as stated, this way they will at least be able to earn the rate of profit on the working capital—and more besides, to whatever extent Big John charges a price that more than equals the costs of operating Little Joe's plant plus allowance for a competitive rate of profit on the working capital that must be tied up. (From the perspective of a later owner who acquires Little Joe's plant at the bargain prices of a bankruptcy sale, practically all such additional proceeds may constitute profit.⁴⁰)

If Big John does not want to wait until Little Joe's capacity has worn out before he raises his price, he may consider buying Little Joe out. Given the enormous financial burden of holding his own price down for so many years, while waiting for Little Joe's capacity to

wear out, it would certainly be much more sensible to buy Little Joe's capacity even at a premium price—above what Little Joe himself had paid for it. Of course, if this is what Big John were to be accused of, it would represent a dramatic reversal of the predatory-pricing doctrine. Now, instead of being accused of eliminating his competitors by charging ruinously low prices, he would be accused of eliminating them by buying them out at premium prices for their assets.⁴¹

But neither method can actually pay Big John if his goal is to profit by imposing arbitrarily high prices. This is because both methods imply that later on, once Little Joe's capacity is out of the way by one method or the other, it is absolutely *necessary* for Big John to charge a premium price merely in order to recoup the reduction in profits he has sustained or the premium price for Little Joe's assets that he has paid. But any premium price he charges in the future, after Little Joe's capacity is out of the way, will only serve to attract *new competitors*, to whom the premium price will offer the prospect of a premium rate of profit. Because of its highly self-destructive nature, and for all of the other reasons explained, these competitors cannot be kept out by the fear of still more predatory pricing. The fact is that the permanent, long-run price that Big John can obtain is limited by the costs of production—the full costs—of potential new entrants, together, of course, with an allowance for the competitive rate of profit on their capital.⁴² These costs set an objective limit above which the price cannot be maintained in the absence of legal protection from competition—namely, that provided by monopoly according to the political concept. As a result, Big John cannot in fact later on charge the premium price that is necessary to recoup the profits he must forgo or the additional expense he must incur.

Thus, even if Big John were able to succeed in driving out his smaller rival or rivals, he would have very little to gain by doing so. His gain would merely be their share of the market, at selling prices not significantly higher than the selling prices that prevailed before he began his effort to drive them out. In terms of our previous example, all that he could gain by years of selling his own 9 units at a loss, or at least at a profit of much less than 20¢ per unit, while he was keeping Little Joe's capacity out of operation, is a profit of an additional 20¢ on the extra unit he was finally able to supply in place of Little Joe. For his price could not significantly exceed the \$1 that prevailed before he cut in order to drive Little Joe out.

More Than One Firm in an Industry as the Normal Case

A major implication of the preceding discussion is that it normally does not pay a firm to attempt to gain the

entire market even of the particular industry in which its comparative advantage lies. In the great majority of cases, of course, it is simply not possible for a firm to gain the entire market of its industry—it is not in a position to outcompete all the other firms, and there are other firms in its industry whose interests are not served by merging with it. But even apart from these factors, even if the firm in question is the most efficient in its industry, once it achieves a certain relative size, whether 60 percent, 80 percent, or 90 percent of the industry's market, gaining the remaining share of the market simply does not constitute enough of a prize to make it worthwhile.

If the remaining, relatively small share of the market is all that is to be gained, it does not pay the large firm to cut its price and reduce its profits on its much greater volume. Its actual interest will lie with the highest price it can obtain that is consistent with its small competitors (and potential competitors) not being able to make enough profit to accumulate the capital required to become more efficient and thus to offer it serious competition. In other words, its interest will lie with setting its price not too far above the full costs of its less efficient competitors or potential competitors, and making the highest possible profits it can by reducing its own costs of production as far below theirs as possible. So long as no one else can make substantial profits at the price it charges, it has no incentive to reduce its price further for the sake of gaining their small volume of business. Its policy will be to allow its small competitors to survive on the most favorable terms short of their rapidly accumulating capital. It will reduce its price only insofar as it perceives a likelihood of the costs of production of its competitors or potential competitors falling. (Sooner or later, in a free economy, this will happen, and it will have to reduce its price. But then, if it manages to retain a cost advantage by having further reduced its own costs of production—which it is motivated to do—it will cut only to the point of once again preventing others from rapidly accumulating capital.)

The exception to this rule of the large firm not disturbing its less efficient small competitors is the case in which, by charging a price below their costs, a vast expansion in the total market of the industry can take place, from which it will be able to benefit substantially. If, for example, at a selling price of 85¢ rather than \$1, the quantity demanded of the industry as a whole expands by a factor of two or three, and Big John is meanwhile able to achieve further economies of scale and reduce his unit cost to 75¢ or even 70¢, then, indeed, it will pay him to undercut his small rivals and drive them out of business (or buy them out). But his motive here is not to gain the piddling volume of his small competitors,

in order then to jack up his price to a higher level than ever before. On the contrary, it is to gain the vast increase in the market of the industry as whole, which can only be done by charging a *permanently lower price*.

But even in this case, becoming the sole producer would not pay if the large firm's cost advantages are of a kind that can be patented and thus shared with other producers in exchange for royalty payments. For then, the firm could make additional profits on 100 percent of an expanded market without having to accumulate by itself all the capital required to supply the market.

If the only substantive gain from price cutting is the volume of business presently carried on by one's competitors, then it follows that it is more efficient *small* firms that have much more to gain by following an aggressive pricing policy than more efficient large firms. A large firm, with 90 percent of the market, has only the 10 percent share of its rivals to gain. But a small firm, with 10 percent of the market, has the *90 percent* share of its rivals to gain. Such a small firm will be much more intent on expanding its share of the market than the large firm.

Thus, this discussion has demonstrated further inherent limits to economic concentration under capitalism, even within a given industry.

And in the light of this discussion, it should come as no surprise that historical research has now established that the old Standard Oil Company (for which, of course, the "Big John" of our examples was a stand-in) *never actually engaged in a policy of predatory price cutting*.⁴³

"Predatory Pricing" in Reverse: The Myth of Japanese "Dumping"

It is ironic in the extreme, that after generations of claims about the predatory-pricing powers of the Big Johns of the world versus the helpless Little Joes of the world, the enemies of capitalism have now done a complete about-face. Now, at least in the case of Japan, they claim to fear the predatory-pricing powers of Little Joes against Big Johns. This new doctrine is manifest in the claims that the economic success of Japanese firms, that only a few decades ago were economically insignificant in comparison with their American counterparts, is the result of Japanese "dumping"—i.e., selling below cost, i.e., "predatory pricing." Yes, now we are asked to believe that the piddling Toyota and Nissan corporations of the 1950s and 1960s, and the piddling Nippon Steel Corporation of the same period, and their piddling counterparts in numerous other industries, have driven out of business or come close to driving out of business one American industrial giant after another. Poor General Motors, poor U.S. Steel, poor whoever—so the story goes—they could not stand the losses inflicted on them

by year after year of "dumping" by Japanese firms that were only a fraction of their size.

No, it may be said, not dumping on the part of small Japanese firms acting on their own, but dumping made possible by subsidies provided by the Japanese government, guided by its nefarious *Ministry of International Trade and Industry*.

Such a tale of Oriental intrigue would deserve to fail even as a Charlie Chan story. What it overlooks, of course, is that the resources at the disposal of the Japanese government have been entirely dependent on the success of Japanese business, which has not operated at losses in its export trade but at very high profits, based on a combination of low costs of production and high quality of products. The Japanese firms may often have sold below the costs of their unionized and otherwise hamstrung American competitors, which came more and more to be managed by incompetents whose leading skill lay in such things as pacifying government regulators rather than in successfully running a business. But rarely if ever did they sell below their own costs.

Only to a fascistic-type mentality imbued with a belief in government omnipotence can it seem reasonable to attribute the success of the Japanese economy to the guidance and subsidies of a government ministry.⁴⁴ The truth is, to whatever extent the Japanese government has diverted Japanese businesses from the path they would have followed strictly on the basis of profit-and-loss considerations and has provided them with subsidies, the success of Japanese business has been less than it otherwise would have been. This is the case because such interference only serves to make firms earn lower profits than they otherwise could have earned and makes it possible for inefficient producers to survive by covering their losses on the basis of taxes taken from the profits of efficient producers. Given the enormous success of the Japanese economic system, such interference, while it may have existed to some extent, could not have been very significant. The success of the Japanese economy is attributable to those elements of it that are consistent with freedom and profit making, not to violations of freedom, not to the earning of lower profits rather than higher profits, and not to the payment of subsidies to cover losses.⁴⁵

The Chain-Store Variant of the Predatory-Pricing Doctrine

The predatory-pricing doctrine must be examined further insofar as it is the case that the larger firm is larger by virtue of its presence in more than one market—for example, chain stores that compete with local merchants, or conglomerates that compete with smaller firms in a variety of different industries. In such cases, of course, if

the larger firm were to slash its price for the purpose of making its smaller rival run at a loss, it would not have to suffer a reduction in its own revenues and profits in proportion to its overall greater size, but only in proportion to its greater size in the particular market concerned.

Here, the argument goes, the large firm is able to cover its losses in the particular market out of the profits it earns in all its other markets. It is able to bring overwhelming resources to bear, and thus not only to drive out its small rivals in one market at a time, but also to keep out all potential new entrants by the mere threat of dipping into its vast treasury and inflicting losses on them.

It was popular at one time to accuse the A&P Company, which for many years was the largest retail grocery chain in the United States, of having followed this policy against neighborhood grocers. The accusations seem to have died down in the years since the company lost that eminent position as the result of a competition that the supporters of the predatory-pricing doctrine must judge to be virtually incapable of having occurred.

An essential fact that must be pointed out in cases of this kind is that the far greater part or, indeed, almost the whole of the profits and capital of the "big, rich firm" is *irrelevant* to its ability to sustain temporary losses in driving its smaller, poorer rivals out of business. The truth of this proposition can be understood by imagining that on the one side is A&P, with \$1 billion of total capital invested in a thousand stores nationwide, and on the other side a small grocer and his wife, with perhaps only \$50,000 of capital invested in their one little store.

This case, of course, is similar to the cases we have already considered, insofar as in slashing its price A&P will have to suffer a reduction in revenues and profits perhaps twenty times as great as the reduction in revenues and profits it can impose on the small store. (This ratio is implied in the fact that A&P's assumed overall total of \$1 billion of capital is supposed to be invested in a thousand stores. The resulting \$1 million average investment per store is twenty times larger than the assumed investment of the small grocer and his wife. To the extent that the larger investment implies a larger volume of business, the losses of A&P must be a multiple of the losses of the small competitor.)

The special fact that must be recognized in the present case, however—a fact that would be critical even if in the particular local market the two firms had invested the same amount of capital and did the same volume of business—is that almost all of A&P's billion and the profits it may make in its other 999 stores are *irrelevant* to what it can afford to lose in this particular location. To demonstrate this conclusion, it is only necessary to assume for the moment that A&P can actually succeed in driving out its small rival or rivals and thereafter keep

out all new rivals by the mere threat of ruining them. If it really could do this, it would forever after earn a premium profit in this one location. But precisely that is the point—it would be a premium profit *in only one location*. Such a premium profit is surely quite limited—perhaps an additional \$100,000 per year, perhaps even an additional \$500,000 per year, but certainly nothing remotely approaching the profit that would be required to justify the commitment of A&P's total financial resources.

And now the question arises, just how much is it worth temporarily losing in order to secure such an extra profit? The temporary loss must be regarded as an additional investment, made for the purpose of later on adding to profits.

True enough, A&P has \$1 billion in capital, and its total annual profits may be on the order of \$100 million or even \$200 million or more. But it could never pay to temporarily lose—to invest—sums of such magnitude for the sake of earning an extra \$100,000 or \$500,000 a year, even if these latter sums could be earned every year thereafter forever. Each individual branch of a business must be judged on the basis of its own profitability and must be profitable in its own right, if the investment in it is to be justified. The measure of how much it pays temporarily to lose in order to increase profits later on, is provided by the going rate of profit on capital in the economic system. If the going, average rate of profit or interest is, say, 10 percent a year, then a \$500,000 annual amount of profit or interest can be made by the investment of \$5 million. This sum—\$5 million—is then the upper limit of what it pays temporarily to lose, in order to eliminate competitors in this one location. By the same token, if the extra permanent annual profit in this one location will only be \$100,000 then the most it pays temporarily to lose in eliminating competitors is \$1 million.

These sums—\$5 million and \$1 million—are the respective capitalized or present values of \$500,000 and \$100,000 a year forever, if the annual rate of return on capital is 10 percent. To the extent that it is necessary to lose sums larger than these in order to secure the \$500,000 or \$100,000 higher profits every year, the effect is that the firm ends up earning a *below-average rate of profit on its capital* in this investment. It earns less on the capital in question than it readily could have earned. The investment is a bad investment.

It cannot be stressed too strongly: all of A&P's billion of capital and all of its tens or hundreds of millions of total annual profits beyond these \$5 million or even just \$1 million of capital are simply irrelevant to its ability to make a worthwhile investment in this case. A&P cannot afford to regard more than these strictly limited sums as

available for a temporary loss. If it loses any more than these sums, its investment is a poor one even if it succeeds in its alleged goal of driving out and keeping out everyone else and becoming the “monopoly” supplier in the area. This is because in such conditions it would end up earning a below-average rate of profit despite its having secured a local “monopoly.” For example, if it temporarily loses \$2 million in order thereafter to earn an additional \$100,000 a year in profits forever, and actually succeeds in earning such profits while the going rate of return is 10 percent, the result is that it ends up earning only a 5 percent rate of return when it could have earned a 10 percent rate of return. Exactly the same result applies if it temporarily loses \$10 million in order to end up earning an additional \$500,000 a year forever.

An equally important implication of these facts is that everyone contemplating an investment in the grocery business who has an additional \$5 million or even just \$1 million to put up *is on as good a footing as A&P* in attempting to achieve such additional profits. For it simply does not pay to invest additional capital beyond these sums. In other words, the predatory-pricing game, if it actually could be played in these circumstances, would be open to a fairly substantial number of players—not just the extremely large, very rich firms, but everyone who had an additional capital available equal to the limited capitalized value of the “monopoly gains” that might be derived from an individual location.

And this very circumstance helps to explain why a policy of predatory pricing cannot be pursued, even in limited areas, one at a time. For what must happen if a company such as A&P were to attempt it? It loses, let us imagine, \$500,000 in eliminating the competitors who were on the scene when it made its initial appearance in the area. Now, if the capitalized value of becoming the sole seller is \$1 million, it can afford to lose only an additional \$500,000; if the capitalized value is \$5 million, it can afford to lose an additional \$4.5 million. But in either case, what is its position in comparison with any outside entrant who has his full \$1 million or \$5 million available?

Such an outsider is now in a position in which, from the point of view of ending up with an investment that at least yields the going rate of return, he can afford to lose more than A&P for the prize of becoming the sole seller. Of course, if he pursues this policy, he in turn will find himself in the same position in relation to still another outsider—all of which means that there is no way of actually securing the kind of premium profits imagined in this example, and that all that can result from the attempt is the pouring of money down a bottomless well. As we have seen before, whoever would attempt it, would find himself in the position of having made a larger-than-necessary capital investment, which he would

later *need* to recover through higher-than-necessary prices and more than a competitive rate of profit, but would be unable to recover in the actual conditions of the market. The capital he expended in the effort to achieve the illusory extra profits would place him in the same position as someone who had constructed his store or bought the land for it at an unnecessarily high price. This is certainly not a formula for growing rich.

Contract Pricing

As I have said, it should not be thought that after having gone to the expense of driving its initial rivals out of business in a particular market, a very large firm might be able to secure premium profits by a policy merely of threatening to lose whatever sums might be required to inflict losses on potential new competitors and thus keep them out by sheer intimidation, with the result that it would not be put to the actual expense of major losses very often. If it is going to charge prices higher than those at which outsiders would be profitable, it will often be put to the test, and suffer accordingly—usually to a considerable multiple of whatever losses it may be able to inflict on its smaller competitors. In fact, it is often extremely easy to overcome any such attempt at intimidation. Apart from everything else I have described, all that would need to be done is for a competing supplier to sell his product *under long-term contract*.

Such a competitor can offer a price that is equal to his cost plus an allowance for the going rate of profit. And he can offer it for the life of his plant. (If he already has a plant and were the object of predatory price cutting, it would pay him, if necessary, to enter such an agreement at any price above his operating costs plus allowance for the going rate of profit on his working capital.) The contract can give the buyers the right not to buy from him—if the alleged predator firm or anyone else is currently charging prices low enough to make dealing with them more attractive. In this case, all that need be required of the buyers is that they pay a relatively modest penalty charge for the units they do not take—a charge just sufficient to cover the supplier’s costs of being in the business and earning the going rate of profit on the capital he must tie up.

Such a charge would exclude any cost of materials or direct labor, since no product would actually change hands, and all but a skeleton level of administrative overhead. In terms of our earlier example of Big John and Little Joe, a new Little Joe, contemplating entry into the field against Big John, could make a contract in which he agrees to sell a unit of his product at \$1 for the life of his capacity, and to accept a fee of, say, 20¢ for each unit not bought. The 20¢, or whatever the comparable figure might be, would cover Little Joe’s depreciation charges,

the cost of maintaining a minimal organization in being, and the profit on the capital invested in the plant, which might have to function sometimes on a standby basis only. (If Little Joe is already in the business, then, depending on his operating cost, it might be worth his while to agree if necessary perhaps to a price as low as 90¢ or even 85¢, and a penalty charge of as little as 10¢ or even 5¢, since his investment in plant has already been made and it represents the lesser loss to accept such terms than simply to go out of business.)

Under such an arrangement, the small competitor's position is made secure, and the buyers are able to place a permanent upper limit on the price they have to pay. If Big John is to obtain their business, he must offer a price that is lower than Little Joe's by more than the penalty charge, which means that he ends up financing the penalty charge. (He ends up financing it, because once his price falls below Little Joe's by the amount of the penalty charge, the buyers save in the lower price as much as they pay in the penalty charge.) If Big John does not wish to price that low in order to obtain their business—if he wants their business at a price close to Little Joe's full price—the only way to obtain it is by offering it on a *permanent* basis. This means that Big John will have to offer long-term contracts with a specified price. In that way, upon the expiration of the life of Little Joe's capacity, he might obtain the latter's business if his long-term contract price is lower than little Joe needs to make replacement worthwhile. But, for the reasons explained, it is unlikely that it will pay Big John to reduce the price on his vastly greater volume in order to obtain Little's Joe's modest share of the market.

At the retail level, contract pricing might take the form of customers joining a buyers' club, for which they pay a flat fee that defrays the seller's costs of staying in business and that guarantees them the right to buy the item at a low price. It is worth noting in addition that at the retail level elements of consumer tastes and preferences enter which almost always establish niches of small competitors that are impossible to dislodge even with substantially lower prices that are permanent. For example, there are all kinds of small stores that have stayed in business through offering greater convenience and more personal service and so forth, despite much lower prices being charged by the chain stores and department stores. Starting from this relatively secure base, such stores are in a position to take away a substantial volume of business from the chains and department stores, should the latter significantly increase their prices.

The Predatory-Pricing Doctrine and the Inversion of Economic History

As previously indicated, the implication of the pred-

atory-pricing doctrine is that real costs and prices both in retailing and everywhere else have tended to increase because of the alleged monopolistic character of the chain stores and of big business in general. In the view of the predatory-pricing doctrine, the development of chain stores and big business does not have any basis in greater economic efficiency, but serves only as a means of raising prices. The implication of the doctrine is that from the point of view of the consumers, the days when all that existed were local general stores, whale oil, and blacksmith shops were the good old days. These days have passed because those suppliers were put out of business by predatory pricing. Now all that exists is price gouging.

It is difficult to imagine a view of things more at odds with the facts. But this is the view implied by the predatory-pricing doctrine. It totally ignores the efficiencies of the chain stores and of big business in general, and that the firms which became big did so by providing better products at lower costs of production. Typically, such firms did not start out as big businesses, but *became* big businesses on the basis of the high profits they earned by virtue of their greater efficiency and which they constantly plowed back. And those firms which began as the result of mergers of already existing firms grew much further—both in terms of the quantity and quality of their output and in terms of their efficiency and capital investment. It is impossible to reconcile the actual economic expansion—the constant increase in capital invested and the constant fall in real costs and prices—throughout the domain of big business over the last five generations, with the contention that big business achieves high profits by means of high prices based on diminished production.

The Myth of Predation With Respect to Suppliers

A notion similar to the predatory-pricing doctrine is the belief that large firms are in a position to deprive their small competitors of access to vital supplies. By means of threatening to withdraw their own business, or by means of bribery, they allegedly induce such suppliers either to refuse to deal with the small firm or to do so only on terms that are unprofitable to it.

The fallacy present in this belief is essentially similar to that which exists in the predatory-pricing doctrine. It overlooks the fact that if the large firm seriously wished to pursue such a policy, it would have to make dealing with it rather than the small competitor more profitable to *every actual and potential supplier* to whom the small competitor might turn, and to offer more to them not only than the small competitor is currently capable of doing, but also is potentially capable of doing in the future.

It must be realized that the small competitor only needs to find *one* supplier, and that to stop him from

doing so, the large firm must close off *every* actual and potential supplier. Moreover, to whatever extent the small firm offers the prospect of becoming larger and thus of offering more business to a supplier as time goes on, it is the profit on that volume of business that the large firm must exceed in its offers.

Furthermore, when one takes into account the fact that the purpose of the large firm in driving out the small firm is supposed to be to sharply increase the price of the product, the position of the small firm must be regarded as all the more secure. This is because the prosperity of the industry's suppliers then depends on the continued existence of competitors to the large firm. As previously explained, if the large firm were actually to be capable of succeeding in raising the price, the effect would be a smaller quantity of the product demanded and thus less demand for the product or service of the suppliers. In other words, the suppliers' market depends on the continued existence of the small firm in these conditions. And that is why, indeed, they can be assumed to be an actual *ally* of the small firm, rather than a partner in its destruction.

While the multiple of cost to the large firm is increased to the degree that its small competitor has access to a larger number of suppliers or potential suppliers, it should not be assumed that if there are only few suppliers or potential suppliers, this represents any kind of advantage to the large firm. On the contrary, even if there were only some definite, delimited number of suppliers or potential suppliers who would need to be secured against the small firm, the large firm would be unable to take comfort in that fact. The consequence would be that any one of the suppliers or potential suppliers with sufficient capacity to meet the requirements of the small firm would be in a position to demand a lion's share of whatever additional profits might be earned by virtue of the absence of the small competitor and the consequent alleged ability to charge substantially higher prices. In other words, since the large firm's extra profit would depend on the cooperation of *all* of the suppliers and potential suppliers, *each of them* would be in a position to demand the greater part or almost all of the presumed extra profits.

The Myth of Standard Oil and the South Improvement Company

In the light of the above, one can regard the story of Standard Oil and the South Improvement Company as a historical fable, at least as far as the interpretation goes that is usually placed upon it. According to a typical account, in a widely used textbook of economic history:

In 1870 Standard Oil was producing about 10 per cent of the country's output of refined oil. This quickly increased to 20 per cent by an ingenious and notorious scheme

involving the South Improvement Company in 1872. Refiners associated with the South Improvement Company were to receive rebates, presumably for acting as "eveners" in the oil traffic pool formed at the same time among the Pennsylvania, New York Central, and Erie Railroads. The open rate on crude oil by rail from the oil regions in western Pennsylvania to Cleveland was to be 80 cents per barrel, and the open rate on refined products from Cleveland to New York City was to be two dollars (\$2.00) per barrel. Thus the combined open rate was \$2.80. The open rate was the same to all shippers, but the members of the South Improvement Company were to receive a secret rebate of 90 cents (40 cents on crude and 50 cents on refined products). In addition to a rebate on all their own shipments, members of the South Improvement Company were also to receive the same rebate on all petroleum shipped by their competitors. Thus the harder their competitors worked, the more money Rockefeller and his associates would make. . . .

Armed with this contract, Standard representatives bought out most of their competitors. Within three months twenty-one of twenty-six Cleveland refiners went out of business. Their plants were either junked or put into use by Standard Oil producers. Although the agreement was signed between the railways and the South Improvement Company the scheme never actually went into operation so far as railway rates were concerned. Yet it was fully effective in achieving its purpose: the elimination of competition.⁴⁶

The meaning of these passages is that Standard Oil somehow managed to obtain an arbitrary discrimination in railroad rates in its favor, for the purpose of eliminating its competitors. Interestingly, the passages note that at the time Standard was not even a particularly large firm (it had only 10 percent of the market), and the railroads did not actually increase rates to Standard's competitors, but cut them to Standard. Apart from a reference to "acting as 'eveners,'" the meaning of which is left unexplained and which is dismissed contemptuously, no explanation is offered of why the railroads would do such a thing. It is apparently thought to be sufficient merely to conjure up an aura of big business and sinister machinations, and to let it go at that.

Without having investigated the historical facts, but approaching the matter with a framework of a knowledge of economic principles, I am confident that if the actual facts were known, an entirely different interpretation would have to be placed upon the episode than the one in the above passages. My confidence is comparable to that of a natural scientist upon hearing a tale of some miracle. He knows automatically that a rational explanation is to be found.

If the episode occurred at all (and the admission that "the scheme never actually went into operation" indicates that perhaps even this should be questioned), then I would offer the following hypothesis. Namely, that Standard Oil devised a plan for regular large-scale ship-

ments of oil and oil products which substantially reduced the railroads' costs of transportation and, at the same time, gave promise of a substantial increase in the total volume of shipments. In return, Standard deservedly received the rebate. It received a rebate on its competitors' shipments as well, insofar as its transportation plan made it possible for the railroads to save money on their shipments by tying them into Standard's plan. The basis for the buyout of most of its Cleveland competitors was probably the fact that the transportation plan could be made more effective by making their volume directly subject to its control. On the basis of prospective major cost savings in transportation, Standard was able to buy out the competitors at prices profitable to them.⁴⁷

8. Marginal Revenue and the Alleged "Monopolistic Restriction" of Supply

The doctrine of an alleged tendency toward a growing concentration of capital in fewer and fewer hands—whether it is to be achieved by means of mergers or by means of predatory price cutting—can now be judged to have been laid to rest. Yet the economic concept of monopoly advances another claim, that is less sweeping, but still quite serious. This is the doctrine that to the degree that a firm is large relative to the size of the market it serves, it is motivated to restrict its production to a quantity of product that is less than what in some sense it "should produce."

The following example provides an illustration of this doctrine in its comparatively more reasonable form. Thus, let us imagine an industry in which there is only a single firm—an out-and-out "monopolist," according to the economic concept of monopoly. At present, this firm produces an output of 100 units of product, which it sells at a price of \$15 per unit. Its cost of production is \$8 per unit. Thus, its sales revenues are \$1,500, its total cost is \$800, and its profit is \$700. The firm is considering the question of whether or not it should produce and sell a second 100 units of its product. If it does, it will have to reduce its selling price to something less than \$15. Let us imagine that \$9 will be the price necessary to attract buyers for a total of 200 units. We can assume that the firm's cost of production per unit will remain at \$8.

I have chosen to assume that the price will have to be \$9 and that the cost per unit will remain \$8 because these figures imply that the production of the second 100 units, if considered in their own right—that is, independently, apart from the effect on anything else—is *profitable*. The second 100 units will bring in sales revenue of \$900 and will be produced at a cost of \$800. Thus, they will bring in a net profit of \$100, which can reasonably be assumed to constitute a sufficient amount of profit to constitute

the going, competitive rate of profit on the capital which must be invested in their production. Consequently, by the ordinary standard of profitability, this second 100 units should be produced.

Nevertheless, argue the supporters of the economic concept of monopoly, our firm will find it unprofitable to produce them. This is because it must consider something besides the profitability of producing the second 100 units in their own right. It must also consider the effect on its profits of having to sell the quantity it is already selling, namely, the first 100 units, at the reduced price of \$9. This aspect of the situation represents a \$600 *reduction* in its profits. This is because instead of selling those first 100 units at a price of \$15, and thereby bringing in sales revenues of \$1,500, it now must sell those first 100 units at a price of only \$9 and thus earn sales revenues of only \$900. Given its total cost of \$800 to produce the first 100 units, this means that the profit it earns on them falls from \$1,500 minus \$800 to \$900 minus \$800, viz., by \$600.

This fact, it is held, far outweighs the fact that the sale of the second 100 units nets a profit of \$100, for the gaining of this \$100 profit requires the simultaneous reduction of \$600 in the profits already being earned on the first 100 units. And thus, the effect of expanding its production from 100 to 200 units is, for this "monopoly" firm, to reduce its overall, total profit from \$700 to \$200—an overall, net reduction of \$500 in its profits. As a result, it is held, it will not produce the second 100 units. It will prefer instead to keep its output at 100 units and its price at \$15. And the buying public will thus be correspondingly deprived. Table 10-1 summarizes all the relevant data.

The table includes the headings "Marginal Revenue" and "Marginal Revenue per Unit." Marginal revenue is *the change in total revenue that accompanies a change in quantity produced and sold*. In this case, it is \$300. In selling 200 units at \$9 per unit, instead of 100 units at \$15 per unit, our firm would end up increasing its total sales revenue by only \$300, because the \$900 received for the second 100 units of its product would be accompanied by a \$600 reduction in the revenues received for the sale of its first 100 units. Marginal revenue per unit is simply the total marginal revenue, in this case \$300, divided by the additional number of units, in this case 100 units.

The relevant consideration for our firm in deciding whether or not to increase its production—and, indeed, for any firm that must reduce the selling price of its product in order to sell a larger quantity of it—is not, it is held, whether the new selling price exceeds the unit cost of the additional products by enough to provide a competitive rate of profit. The relevant consideration is,

Table 10–1
Marginal Revenue and the Alleged Incentive of a “Monopoly” Firm
to “Restrict” Its Production

Quantity	Price	Total Revenue	Marginal Revenue	Marginal Revenue per Unit	Unit Cost	Total Cost	Profit
100	\$15	\$1,500	—	—	\$8	\$800	\$700
200	\$9	\$1,800	\$300	\$3	\$8	\$1,600	\$200

allegedly, whether or not *the marginal revenue per unit*, rather than the price, exceeds the unit cost of the additional output. The marginal revenue per unit takes into account the drop in price on the quantity that is already being sold. In the present case it is \$3, reflecting the combined effect of receiving a selling price of \$9 on the increase in quantity sold from 100 to 200 units and having to accept a price reduction of \$6 on the initial 100 units.

This belief, that marginal revenue, rather than price, is the relevant item for a firm to compare with its cost in deciding whether or not to expand output can be called *the marginal-revenue doctrine*.

It is on the basis of the marginal-revenue doctrine that it is held that to the degree that a firm is large relative to the market it serves, it is correspondingly less motivated to expand its production. To the degree that the firm is large, it is argued, the more will its marginal revenue per unit accompanying any increase in its production fall short of the selling price that accompanies that additional production. For it will experience the fall in price that is associated with its additional production on a correspondingly larger initial quantity. Thus, the more strongly will it be motivated not to expand its production, despite the fact that by the standard of the profitability of the additional output considered in its own right, output should be expanded.

A “monopolist,” it is held, has the least incentive to expand, for he must experience the price reduction on the full quantity of the product presently sold. But a firm that initially produces and sells only half, or even a tenth, of the total output of an industry, can also have a powerful incentive not to expand its production, according to the marginal-revenue doctrine.

This last claim can be illustrated by imagining that the initial output of the industry is 10 times larger than previously assumed—1,000 units instead of 100. Our firm produces 100 units out of the 1,000 and is contemplating whether or not it should produce 200 units. If the

production of this second 100 units for our firm, which at the same time is the production of an eleventh 100 units for the industry as a whole, should necessitate a reduction in the selling price of the industry’s product to \$9, then, it is argued, everything would be just as before from the perspective of our firm. It would allegedly not expand its output because doing so would require too great a reduction in the selling price of the quantity it was already selling.

From the point of view of the supporters of the marginal-revenue doctrine, the only difference between this case and the first case is that the demand curve of the industry is now less elastic. In the first case, it takes a doubling of the output of the industry to necessitate a price reduction of 40 percent. In the present case, it takes an increase in the industry’s output of only 10 percent to necessitate a price reduction of 40 percent. The percentage change in the quantity demanded of the industry’s product relative to the percentage change in the price of the product necessary to achieve that percentage change in quantity demanded—which is the definition of elasticity—is one-tenth as great in the present case.

However, given the *same* elasticity of demand for the product of the industry as a whole, it follows from the marginal-revenue doctrine that the smaller the size of the firm relative to the industry, the greater will be its incentive to increase its production. If we retain the assumption that our firm initially produces 100 units out of an industry total of 1,000, and that the elasticity of demand for the product of the industry as a whole is no lower than it was in our first example, then a 10 percent increase in the industry’s supply, brought about by a doubling of our one particular firm’s supply, will cause perhaps only a 4 percent reduction in the industry’s selling price—viz., from \$15.00 to \$14.40. (The assumption here is that a 10 percent increase in the industry’s supply necessitates a price reduction only one-tenth as great as a 100 percent increase in the industry’s supply—in this case, 4 percent instead of 40 percent.⁴⁸) Thus, in this case, it supposedly

pays the firm to double its output, for it now takes in \$2,880 in sales revenues ($200 \times \$14.40$) and, with total costs of \$1,600, it earns a substantially increased profit of \$1,280 instead of \$700.

Given the elasticity of demand for the product of the industry, the elasticity of demand for the product of an individual firm, it is held, is inversely proportionate to the smallness of its size in the industry as a whole. To the degree that the firm is small, what appears as a large relative increase in its own production is nevertheless a small percentage increase in the production of the industry as a whole, and thus results in a reduction in selling price that is correspondingly small. For instance, in the present example, a 100 percent increase in the firm's own output constitutes a mere 10 percent increase in the output of the industry as a whole and necessitates a reduction in selling price only in accordance with the 10 percent increase in the overall supply of the industry, not a doubling of the supply of the industry. If the firm initially represented 1 percent of the industry instead of 10 percent, then, it is argued, a doubling of its supply would constitute only a 1 percent increase in the industry's supply and would thus be accompanied by the still more modest price reduction accompanying this much lesser increase in the industry's supply. And thus the incentive of the firm to increase its production would be greater still. It is on this basis that contemporary economic theory has long preceded the environmental movement in subscribing to the cliché that "big is bad and small is beautiful"—at least when it comes to business.

It should be observed, however, that there is an important and paradoxical difference between the contemporary economist's and the ecologist's attachment to this cliché. What the contemporary economist is actually criticizing the large firm for is *its failure to produce still more and thus to become larger still*. What he is applauding the small firm for is its presumed readiness to produce more and thus to become larger. There are two elements of paradox present in this. First, if the large firm did produce all that it is supposed to produce—if, for example, in our initial illustration the firm did produce the 200 units and accept the price of \$9—it would then be denounced as a monopoly. Thus, it is denounced as a monopoly if it does produce the extra 100 units, and denounced as monopolistically restricting supply if it doesn't produce the extra 100 units. It is in the same position as the poor Russian worker under the Soviet regime, who was guilty of spying if he came to work early, sabotage if he arrived late, and of having a capitalist watch if he came on time. Second, if it is the case that the large firm will not produce the extra units, and the small firm or new entrant will, then the whole alleged problem simply disappears. The large firm ceases to be

relatively so large, as it holds its production steady and small firms expand or new entrants appear. As far as it exists, such behavior on the part of the large firm would simply be one more reason why there is normally more than one firm in an industry.

The marginal-revenue doctrine is usually not presented in such relatively simple and therefore clear terms as it has been presented here. In particular, no special stress is normally laid on the production of the additional units being profitable in their own right. Thus, the implications of that fact are rarely if ever considered. It is simply established that there are circumstances in which a large firm, especially a "monopolist," could gain more by producing less. But because it has stressed this aspect, the preceding exposition suggests a profound and very obvious difficulty with the marginal-revenue doctrine.

This difficulty can be seen clearly even in the seemingly strongest case in favor of the marginal-revenue doctrine, namely, that of the so-called out and out monopolist, in which there is just one seller. The difficulty is that unless this firm produces a product which others are simply physically unable to produce, or, more likely, are forcibly prevented from producing by the government (rightly so in the case of patents and copyrights), its actual choice is not such as between producing and selling 100 units at a price of \$15 or 200 units at a price of \$9, but between 100 units at a price of \$9 or 200 units at a price of \$9. Apart from the exceptions just mentioned, so long as the second 100 units are profitable in their own right, *they will be produced*. The only question is whether they will be produced by the firm that is already producing 100 units or by another firm. In the latter case, the first firm ends up selling at \$9, but only 100 units instead of 200 units.

The principle here is that where competition is physically possible and is peaceful—that is, in which the same or a similar good is capable of being produced by others without violation of anyone's intellectual property rights—and is legally free, the decision of any seller or group of sellers to produce less, or not to produce at all, cannot lastingly establish a selling price that is above the cost of production, plus allowance for the going rate of profit, of potential competitors. Under such conditions, it is impossible for anyone to charge prices significantly higher than would be required for a potential new entrant into the industry to make a competitive rate of profit—except in the case of temporary scarcity, and except to the extent that one's product may be of premium quality over his.

If one does charge a price above the point an outsider needs to be profitable, the outsider enters, and, for the reasons explained in the preceding section, one cannot then reverse field and resort to the policy of driving him

out by means of ruinous prices. One simply loses volume and must accept the lower price he will charge. *The upper limit to one's price, therefore, is set by the cost of production of potential new entrants.* If one goes higher than their cost plus an allowance for the competitive rate of profit they would require, one loses more and more volume, until one is finally driven out oneself or accepts the fact that one cannot exceed this limit in price.

One's price may certainly be lower than this limit, and will be whenever one has a lower cost of production than the outsiders and it is more profitable to charge a lower price. But it cannot be higher. As previously stated, the cost of production of potential new entrants constitutes an objective given that limits one's price. One's only choice is to sell either a smaller volume at that cost-limited price or a larger volume at that cost-limited price or a still larger volume at a lower price. But one cannot get a higher price.

If one allows for the time that may be required for new firms to enter a field, one can say that irrespective of the elasticity or inelasticity of the demand for the product of an industry as a whole, *the elasticity of the demand for the product of any individual firm, however large, is virtually infinite if it charges a price above outsiders' costs plus allowance for the going rate of profit.* At such a price, or just below it, it can potentially sell the full quantity demanded at that price. Above such a price, it will sell little or nothing.

In the face of competitors already in the field, the pressures for a price limited by outsiders' costs are all the more intense. The pricing of the whole group of present producers must be limited by this consideration even if they were formed into a single combination. Acting separately and independently, however, the acceptance by any of them of the need to make his price conform to the cost of production places the others under a powerful immediate pressure to limit their price in the same way. For whoever charges more than the cost-limited price will immediately lose substantial volume to those who do not (unless his product is of such premium quality over theirs as to justify the premium price he charges).

To state matters further in terms of the concept of elasticity of demand, one must say that under the freedom of competition the elasticity of demand for the product of any individual company or group of companies at a price above outsiders' costs plus allowance for the going rate of profit, is determined by the sum of the elasticity of demand for the product of the industry as a whole *plus the elasticity of supply of competitors and potential competitors.* That is, at such a price, the quantity of the firm's product that is demanded falls not only in accordance with the amount by which quantity demanded from the industry falls, but also by the amount by which the supply

provided by competitors and potential competitors increases, for their sales will be made at its expense. And thus, while the demand curve facing the industry as a whole may be almost perfectly inelastic, or, indeed, actually be perfectly inelastic, the demand curve facing any individual firm in the industry tends to be perfectly elastic at a price above outsiders' costs plus allowance for the going rate of profit.⁴⁹

Competitors' and Potential Competitors' Costs—Ultimately, Legal Freedom of Entry—as Setting the Upper Limit to Prices in a Free Market

The implication of the preceding discussion is that in a free market, prices of products are normally determined by cost of production—if not one's own cost of production, then at least that of competitors or potential competitors, which cost product prices must not exceed by more than an amount of profit sufficient to provide the going rate of profit. It is further implicit in the preceding discussion that *legal freedom of entry is the essential foundation of competitive price determination.* For it is legal freedom of entry that is necessary to make possible the threat of new entrants, whose costs determine the upper limit to almost every industry's prices.

In contrast, the elasticity or inelasticity of demand—that is, the extent of the willingness of buyers to pay higher prices for smaller quantities of the product—usually does not enter into the determination of prices, and, as will be demonstrated later in this section, plays only a limited role even in the cases in which it does enter.⁵⁰ The demand for many goods is extremely inelastic, meaning that if it were possible to achieve even modest reductions in their supply, sharply higher prices could be obtained. All kinds of spare parts, manufacturing components, inexpensive supplies, and necessities fall into this category. Imagine how much every buyer of spark plugs, fan belts, fuel pumps, carburetors, nails, screws, paper clips, bread, and table salt would be willing to pay even for the marginal unit he now buys, if he had no choice. Certainly, it would be a substantially higher price than he does pay in most such instances. Every spare part, if priced on the basis of its own marginal utility, would be worth the full value of the product it restores to operation: e.g., the marginal fan belt or carburetor would have the value of the marginal automobile. And even in the cases in which the present marginal unit might not bring a higher price, a very slight reduction in supply would so elevate the importance of the marginal unit as to bring about a sharply higher price.

Imagine for the moment that because of a very slight reduction in its production and supply, the amount of table salt annually consumed had to be reduced by as little as 1 percent, indeed, by just .1 percent, of what is

presently consumed. Consider how high the price of table salt would have to rise from its present level to make buyers economize on their use of table salt even to this extremely modest extent—to be careful to get more of the salt on the food rather than elsewhere on the plate or on the table cloth. The price of table salt might very well have to go up by a factor of five or ten times or more, to make people conscious of this need to economize on its use, given how cheap it now is.

It should be obvious that what the buyers would be willing to pay for table salt—or any of the other goods mentioned—if its supply were the least bit smaller, is totally irrelevant to the price they actually do have to pay for it in all normal circumstances. Its actual price is set within the much lower limit determined by the cost of production plus competitive profit of potential new producers. And were there only one seller of table salt rather than the comparatively small number that presently exist, and he were subject to the legal freedom of competition, its price would be determined no differently.

Perhaps the most powerful factor operating to keep prices in line with cost of production, irrespective of the elasticity of demand for the product, is the existence of formal or informal contractual arrangements. Prices set by contract are routinely ignored in economic theory, except as an alleged impediment to the adjustment of prices to the currently prevailing market forces. Nevertheless it is vital to recognize the role of contractual arrangements in removing the relative inelasticity of demand as a factor influencing price determination and in making cost of production the determinant of price.

Because of the ability to enter into contractual agreements, buyers can safely rely on small numbers of sellers—indeed, even just one seller—to serve as their source of supply, no matter how inelastic the demand for the good in question may be. The prices set under the contracts are cost-limited prices, in that they are limited at least by the costs of other potential suppliers, and are normally below the prices required by those other potential suppliers for the latter to be sufficiently profitable. (That is why the contracts are made with the particular suppliers they are made with, and not with other, merely potential suppliers.) Although limited by cost, such prices can easily be made to reflect the operation of current market forces, by being allowed to vary with one or more of the prices that enter into the supplier's current costs, and which he is not in a position to determine. For example, a contractually determined price of electric power might contain a provision for variability with the price of coal; a contractually determined price of components or supplies might contain a provision for variability with the price of the principle raw materials used in their production.

The setting of prices by contract, on the basis of cost,

prevents the possible inelasticity of demand for the product from being a factor in setting prices because the sellers are unable to obtain any higher price on whatever quantities they have agreed to sell under contract. Indeed, it may well be the case that the contractual arrangement gives buyers the right to purchase a variable quantity at the contractual price, with the result that, in effect, there are buyers who hold *options* on additional supplies at contractually set prices. In the face of such contractual arrangements, it may simply be impossible for the seller or sellers to reduce the market supply at all. And to the extent that it may still be possible for them to do so—only temporarily, of course—they are placed in a position in which the major beneficiary of their action would not be themselves, but *the buyers who have the right to buy at contractually fixed prices*.

To illustrate these points, let us consider once more our example of the ability to sell 200 units at a price of \$9 and 100 units at a price of \$15. Let us imagine that the firm producing the first 100 units has decided to forestall the entry of an outside firm and itself to produce and sell all 200 units at the price of \$9. Thus, it is the sole supplier of the full competitive quantity at the competitive price.

Contract pricing prevents this firm from deciding from time to time to cut production back to 100 units in order to raise the price back up to \$15. Even if only half of its output—100 of its 200 units—is sold at a contractual price of \$9, it loses any motivation to cut back its production. If it did decide to produce 100 instead of 200 units, then, even without any competitor entering the field, the effect would be that it would sell 100 units at \$9 instead of 200 units at \$9, because those 100 units would be bought by the contract holders at a price of \$9. Contract pricing operates to make the demand curve facing this firm perfectly elastic even in the immediate moment. Because of contract pricing, its choice in the immediate moment is reduced to whether it should sell 100 units at \$9 or 200 units at \$9.

And if for any reason this firm did produce only 100 units, the only possible beneficiaries of the resulting market price of \$15 would be the firm's customers who held contractual rights. They would buy the product at the contractually fixed price of \$9 and would be able to sell it at the higher open-market price of \$15. In these conditions, it bears repeating, even the short-run interest of our firm is to produce and sell 200 units rather than only 100 units. (It should be observed that if our firm decided to produce any intermediate amount of output, between 100 and 200 units, it would gain any higher price only on the quantity it produced in excess of 100 units, while its customers who had contracts gained the rise in price on their 100 units. The profits earned by the cus-

tomers on their 100 units could be used to finance a new competitor or new sources of supply under their own, direct control. The result would be that if our firm did decide to reduce its production below 200 units, it would set the stage for being faced with a new competitor or with a permanent reduction in the quantity demanded from it because its customers developed their own sources of supply—or it would end up having to sell a still larger portion of its output under contract. Or some combination of all three possibilities would result. In any event, the firm would not be able to repeat the procedure and would probably find it inadvisable to resort to it in the first place.)

This example illustrates the fact that in a free market, with substantial portions of output sold under contract, there need be no danger even of short-run arbitrary increases in price—even in situations of the most highly inelastic industry demand and in which there is just one supplier. Thus, even if there were just one producer of table salt, it would probably not be possible for him even temporarily to take advantage of the inelasticity of demand for table salt. His customers—grocery-store chains and wholesale jobbers who distribute to small retail grocers—would almost certainly obligate him to deliver at a contractually set price, limited by the cost of production of other potential producers, a quantity of table salt that, at their option, actually exceeds the quantity that is demanded from them at a normal retail or wholesale price of table salt. In such circumstances, even in this extreme case it would be impossible for the supplier to restrict the supply and raise the price.

Indeed, the fact that the price of table salt and of other goods with a comparably inelastic demand does not periodically shoot up in an effort to exploit the high inelasticity of demand can probably be explained only by the existence of contractual arrangements. For even when such goods are supplied by ten or twenty suppliers, in the absence of extensive formal or informal contractual arrangements, any one of the suppliers would probably be physically capable of reducing the industry's supply by the relatively tiny amount necessary to make its price skyrocket. Contractual arrangements, however, tie the price to cost on such a volume of output that no producer is in a position to reduce the supply below what the market demands at the cost-determined price, or would find it profitable to do so even if he were temporarily capable of doing so. Typically, a reduction in production by any one producer can be offset by an increase in production by others. And even if it cannot, it would not pay him.

The role of cost of production, rather than elasticity of demand, in the determination of prices is further evident in such cases as an excise tax increase on ciga-

rettes. Cigarettes are a good that is faced with a highly inelastic demand and which is produced by only a handful of firms. When the excise tax on cigarettes is increased, the price of cigarettes is correspondingly increased. At the higher price there is very little reduction in the quantity of cigarettes demanded, and the tobacco industry's pretax sales revenues sharply increase. The tobacco industry raises its price when the excise tax is increased because that is a factor raising the costs of doing business of all producers and potential producers.

In the absence of such a factor that increases costs to everyone, the tobacco industry would not be able to raise its price, despite the fact that if it could succeed in doing so all the firms would have sharply higher sales revenues and profits. By the same token, if the excise tax on cigarettes is reduced, or some other development occurs which broadly reduces the cost of providing cigarettes, the price of cigarettes must be correspondingly reduced.

The reason is that the existence of exceptionally high profits not based on any special advantage in cost of production or premium in quality would be an invitation for the entry of one or more new cigarette companies, including all kinds of house brands marketed by retailers. The ability of a tobacco company to retain the volume of business it does with many of its major customers, such as wholesalers and supermarket and drugstore chains, is contingent on the price it charges being reflective of the cost of production on the part of such other potential producers. It is clear that this is a case in which price is governed by cost of production, not by the elasticity or inelasticity of the demand for the product.

It is implicit in the present discussion that a major factor that directly ties the prices of products to their cost of production is *the potential competition which can take place between producers at different stages of the productive process*. If, for example, the tobacco companies were to raise or keep up the price of cigarettes without any objective foundation in the form of higher costs for all potential competitors, their action would be contrary to the interests both of their customers—wholesalers and retailers of cigarettes—and of their suppliers—most notably, the tobacco growers. The higher price they charged would be perceived as an unnecessarily higher cost of doing business by the cigarette wholesalers and large retailers, who would be on the lookout for lower-cost sources of supply. At the same time, when passed forward to the consumer, the higher price would result in some reduction in the quantity demanded of cigarettes and thus in some reduction in the demand for and price of cigarette tobacco. Thus, tobacco growers would have a powerful interest in the reduction in the price of cigarettes to the consumer, in order to restore the demand for and price of their tobacco leaf. If the tobacco companies

want to avoid giving the tobacco wholesalers and retailers a motive to move backward, and the tobacco growers a motive to move forward, into cigarette manufacturing, they must keep the price of cigarettes below the level of outsiders' costs plus allowance for the competitive rate of profit. The same principle applies, of course, to producers at different stages in the productive process in all other industries.⁵¹

Ricardo and Böhm-Bawerk on Cost of Production Versus the Elasticity of Demand

The much-maligned doctrines of the eminent classical economist David Ricardo on the subject of cost of production as a determinant of prices should be taken as the basis for the critique of the marginal-revenue doctrine rather than support for Marxism. In a letter to Malthus, he writes in criticism of Say:

He certainly has not a correct notion of what is meant by value, when he contends that a commodity is valuable in proportion to its utility. This would be true if buyers only regulated the value of commodities; then indeed we might expect that all men would be willing to give a price for things in proportion to the estimation in which they held them, but the fact appears to me to be that the buyers have the least in the world to do in regulating price—it is all done by the competition of the sellers, and however the buyers might be really willing to give more . . . they could not, because the supply would be regulated by the cost of production⁵²

This and similar passages are perfectly correct if understood not as presenting a universal and primary proposition, but one which is descriptive of conditions in the case of reproducible goods for which the demand is highly inelastic. In such cases, the valuations of the buyers are, indeed, clearly rendered irrelevant. The freedom of competition prevents the sellers from exploiting the inelasticity of demand and obtaining a price that would come up to the marginal valuation of the product by the buyers (or their marginal valuation of a slightly reduced supply). Competition sets the price at the much lower point corresponding to the cost of production of the item.

Observe. There is no necessary implication here that cost of production can make anything *more valuable* than corresponds to its marginal utility, but only that it can make something *less valuable* than corresponds to its direct marginal utility. Understood in this way, Ricardo's doctrine is perfectly reconcilable with the views of Böhm-Bawerk, despite the latter's espousal of the seemingly totally contradictory proposition that "price is actually limited and determined by the valuations on the part of the buyers exclusively."⁵³

In advancing this proposition, Böhm-Bawerk has in mind merely *the personal, subjective valuations* of the

sellers. These he rightly dismisses as a determinant of prices, on the grounds that in modern conditions of division of labor, in which goods are produced in quantities far beyond any possible personal requirements of their producers, the marginal utility of almost the whole supply of most goods is virtually zero to the sellers.⁵⁴ Determination of price by cost of production, however, is something very different than its determination by the personal, subjective valuations of the sellers. Indeed, Böhm-Bawerk himself demonstrates precisely how determination of price by cost of production is fully consistent with determination by the marginal utility of products to buyers, and is actually *an essential aspect* of that determination.

Because so many who claim to be Austrian economists have apparently never read Böhm-Bawerk on this vital point, I quote him at length:

Up to this point in our discussion the law of the value of production goods was developed subject to the simplifying hypothesis that every group of means of production admits of utilization only to one very definite purpose. That hypothesis is in real life only very rarely in agreement with the facts. It is preeminently production goods, far more than consumption goods, which are characterized by egregious heterogeneity. The overwhelming majority of them will be capable of service in several productive fields, some are adaptable to thousands of such productive services. Examples are iron, coal, and above all, human labor. Of course, we have to take these factual circumstances into account in conducting our theoretical investigation. We must observe what modifications, if any, affect the law that the value of a group of goods occupying remote orders is governed by the value of their product.

Let us alter the order of the presuppositions of our typical example accordingly. Someone possesses a rather large supply of means of production of second order (G_2). From each of these groups he can produce at will a consumption good of the category A, or one of category B or finally, of category C. He desires, of course, to take advance measures toward balanced provision for his various wants, and will therefore draw simultaneously on various parts of his supply of means of production to produce consumption goods of all three categories. And he will produce amounts in each in accordance with his needs. If there is genuinely balanced provision, the quantities produced will be so regulated that needs of approximately equal importance depend upon the last specimen in each category, and that thus the marginal utilities are approximately equal. In spite of that it is not impossible that there will be differences—possibly even quite considerable differences—in the marginal utilities because, as we already know, the gradation of concrete wants occurring in any one category is not always either uniform or continuous. The first stove in my room will afford me a very considerable utility, say one we might designate with an index of 200. A second stove will afford no utility at all. I shall most emphatically call a halt in providing stoves when I have a single specimen with its

marginal utility of 200, even though in other areas provision for needs may see a dropping off of the average of marginal utility to as little as 120 or even 100. And so it is permissible and necessary, if our example is to be true to nature, to assume that the marginal utility of a specimen will be different in each of the categories A, B and C. Let us call it 100 for A, 120 for B and 200 for C.

Now the question arises, "What is the value, under these circumstances, of a group of means of production, G_2 ?"

We have had so much practice with selective decisions of a similar nature that we can give the answer without hesitation. The value will be equal to 100. For if one of the available groups of means of production should be lost, the owner would naturally shift the loss to the least sensitive area. He would not curtail production in category B where he would be sacrificing a marginal utility of 120, and certainly not in category C where the sacrifice would go as high as 200. He would quite simply produce one specimen fewer of category A where the reduction in well-being is only 100. Let us express it in general terms. *The value of a unit of means of production is governed by the marginal utility and the value of that product which has the least marginal utility among all those products for the making of which the unit means of production could have justifiably been used.*

All the relations which we had declared to be plainly in force with regard to the value of means of production and their products under the simplifying assumption of only a single possible disposition, are therefore generally valid as between the value of means of production and value of its least valuable product.

And what is the situation with respect to the other categories of products, B and C? That question brings us to the origin of the "law of costs."

If under all circumstances the marginal utility attainable by a good within its own category were determinative, then the categories B and C would have to receive a value divergent not only from that of category A, but also from the value of its costs G_2 . B would then have a value of 120, C a value of 200. But here we are confronted with one of the cases where, through substitution, a possible loss in one category is transferred to another, and as a result, the marginal utility of the latter becomes determinative for the other as well. Thus, if a specimen of category C is lost, it is not necessary to forgo the marginal utility of 200 which the specimen would have delivered directly. Instead, it is possible to convert one unit of the means of production G_2 into a new specimen C, and in its place rather produce one specimen fewer in that category in which the marginal utility, and hence the loss in utility is least. And indeed that possibility becomes a reality. The category in question in our example is the category A. Because of the opportunity which production offers for substitution, a specimen C is therefore not valued in accordance with its own marginal utility of 200, but in accordance with the marginal utility of the least valuable related product, the product A; its value is therefore 100. The same applies, naturally, to the value of category B, and would apply generally to every category

of good which is "productionally related" to A, and of which the direct marginal utility is also greater than that of category A.

This leads to some important consequences. The first is that in this way the value of goods having a higher individual marginal utility occupies the same rank as the value of the "marginal product";⁵⁵ and hence also the same rank as the means of production from which both emanate. The identity which exists in principle between "value" and "costs" therefore obtains in this instance as well. But it is to be carefully noted that here the coinciding is brought about in quite a different way from that which was followed in the case of costs and marginal product. In the latter instance the two coincide because the value of the means of production accommodates itself to the value of the product. The value of the product is the determinant factor, the means of production is the factor that is determined. In our present case it is the other way around, and it is the value of the *product* that must do the accommodating. Ultimately it accommodates only to the value of another product. But initially it accommodates also to the value of the means of production from which it emanates and which brings about its substitutional connection with the marginal product. The transmission of value proceeds, so to speak, along a broken line. First it goes from the marginal product to the means of production, fixes the value of the latter, and then ascends in the opposite direction from the means of production to the other products which it is possible to produce from them. In the end product, then, the products of higher immediate marginal utility derive their value from their means of production. Let us translate the abstract formula into terms of concrete practice. Good B or good C is, in general, a product of higher immediate marginal utility. If now we consider what good B or C is worth to us our first response is, "Just exactly as much as the means of production are worth to us from which we can at any moment replace the product." If we then inquire further and ask how much the means of production themselves are worth, we arrive at the marginal utility of the marginal product A. But on innumerable occasions we can spare ourselves this further inquiry. Time and again we already know the value of the goods that comprise the cost, without any necessity for working it out from its foundation and proceeding onward from case to case. And on all these occasions we simply determine the value of products by their costs, and in doing so we are taking advantage of an abbreviation which is as accurate as it is convenient.

And now the whole truth about the celebrated law of costs is revealed. It is indeed quite correct to say that costs govern value. Only it is imperative to remain aware of the limits within which this "law" is valid and of the source from which it derives its virtues. *In the first place* it is only a *particular* law. It is valid only so long as the possibility is present of furnishing, through production, substitute specimens in any quantity and at any time they are desired.⁵⁶ If there is no possibility of substitution, then in the case of each product, value must be determined by its immediate marginal utility in its own category. In that case its value no longer coincides with that of the marginal

product and of the intermediate means of production. Therein lies the explanation of the empirically established principle that the law of costs is valid only for the goods that are “reproducible at will,” and that it is a law of only approximate validity. For it does not bind the goods over which it holds sway to slavishly meticulous adherence to costs. On the contrary, it permits fluctuations above and below such costs, depending on whether production at the moment lags behind demand or outstrips it.

A second and still more important consideration is that even where the law of costs is valid, those costs are not the final, but only an intermediate cause of the value of goods. In the last analysis, they do not give value to their products, but *receive* it from them. That is clear as crystal in the case of production goods for which there is only one productive use. Surely no one will wish to deny that it would be erroneous to assert that Tokay wine is valuable because Tokay vineyards possess value; everyone will concede that the truth is the other way around, and those vineyards have a high value because their product is highly valued. It is just as hopeless to deny that the value of a quicksilver mine depends on that of the quicksilver, the value of a wheatfield on that of wheat, the value of a brickkiln on that of brick, and not vice versa. Only because of the manysidedness of most cost goods is it possible for the situation to present the opposite appearance. As the moon reflects the light of the sun upon the earth, so do the manysided cost goods reflect the value which they receive from their marginal product on their other products.⁵⁷

What Böhm-Bawerk has shown in these passages is that when the price of goods such as fan belts, or anything else whose own, direct marginal utility is extremely high, is determined on the basis of cost of production, precisely then is its value determined on the basis of marginal utility—the marginal utility of the means of production used to produce it, as determined in other, less important employments. The buyer of a fan belt, or whatever, does not pay a price corresponding to the value he attaches to his car, but a much lower price corresponding to the marginal utility of the materials and labor required to produce fan belts or whatever—a marginal utility that in turn is determined by the marginal utility of products other than fan belts or whatever. As Böhm-Bawerk develops the law of diminishing marginal utility, it is no more surprising that the price of vital components and parts, or any necessity, is in conformity with its cost of production rather than its own direct marginal utility than it is that the marginal utility of the water on which our physical survival depends is no greater than the utility of the marginal quantity of water we use. Determination of price by cost is merely a mechanism by means of which the value of supramarginal products is reduced to the value of marginal products. The only complication is that the marginal products in this case are physically different and lie in other lines of production.

Views on costs very similar to those of Böhm-Bawerk

are expressed by Friedrich von Wieser, another leading member of the early Austrian school of economists. Wieser flatly declares “. . . on the whole, the cases where costs directly determine value predominate.”⁵⁸

It should be clear that the notion that cost of production has no significant explanatory role in economics does not come from Böhm-Bawerk and Wieser. It comes from Jevons. It was Jevons who held that the only possible connection between cost of production and price was through the intermediary of variations in supply and that every price is actually determined by the specific demand for and supply of the individual good in question.⁵⁹

The principle actually elaborated by Böhm-Bawerk leads to the surprising conclusion that in one important respect the direct determination of price by cost, rather than by supply and demand, goes even beyond what Ricardo maintained. Namely, it exists even in cases of products like vintage wines, which are capable of being produced only in limited quantities. Ricardo described the prices of such goods as an exception to the general principle and as being determined by supply and demand rather than by cost of production.⁶⁰ It is true that the price of vintage wines is not determined by their cost of *production*. It is no less true, however, that the retail price of such wines is also not determined by the supply and demand for them retail store by retail store.

The actual fact, which is in accordance with the essentials of Böhm-Bawerk’s view, is that supply and demand and marginal utility determine the *wholesale* price of such wines—often at an actual auction, where the bidders are the major distributors, whose bids are limited by the prices they expect the ultimate consumers will be willing to pay. The wholesale price that is determined thus reflects the full range of consumer demand for the wine, not just the demand at any one retail location. The wholesale price, in turn, is then normally the immediate determinant of the retail price at all the individual retail locations. (The retail price, of course, may differ somewhat from location to location, depending on special circumstances). In effect, determination of price by cost is simply determination by supply and demand and by marginal utility *operating across the whole of the relevant market or markets, not just the narrow market immediately concerned*. Cost is what communicates to the narrow, individual market the state of supply and demand and marginal utility in these broader markets.

If contemporary economists had a greater familiarity with the writings of Ricardo and Böhm-Bawerk, they might not find themselves in the embarrassing position of writers such as Samuelson and Nordhaus, who, after devoting chapter after chapter to developing a theoretical analysis that is entirely dependent on the concept of

marginal revenue, are surprised to find that it is largely irrelevant to the real world and that they have no theory to explain the actual facts of pricing. Thus, in describing the actual pricing decisions of businesses, Samuelson and Nordhaus must write:

Here is where the surprise comes:

Armed with the information about sales and costs, you will almost surely never set your price by an *MR* [marginal revenue] and *MC* [marginal cost] comparison. Rather, you will generally take the calculated average cost of a product and *mark it up* by adding a fixed percentage—5 or 10 or 20 or 40 percent of the average cost. This cost-plus-markup figure then becomes the selling price. Note that if all goes as planned, the price will cover all direct and overhead costs and allow the firm a solid profit.

Investigators of actual business pricing policies have testified that corporations often do follow the above-described practice of quoting prices on a “cost-and-markup” basis. Case after case shows that markup pricing is the norm in imperfectly competitive markets.⁶¹

It is one of the great tragedies of contemporary economic theory that it has lost sight of the role of cost of production as the direct determinant of prices of most manufactured or processed goods *precisely under normal conditions of free competition*, which contemporary economists such as Samuelson and Nordhaus erroneously call “imperfect competition.” If a firm can assume that its own costs of production are no higher than its competitors’ or potential competitors’, then in setting its prices in conformity with its costs—that is, above its costs only by enough to earn the going rate of profit—it ensures that it is not likely to be undersold to any great extent, or to attract newcomers to its field. If it can assume that its own costs are significantly below those of its competitors, then, as already explained, it will want to set its price not too far above its competitors’ costs, as a maximum, so that they are not in a position to accumulate much capital and expand at its expense, and also in order not to provide an incentive for others to enter the industry. (If a firm’s costs are above those of its competitors, then except to the extent its product may be of premium quality over theirs, it must simply match the prices they set. It will continue to do so, so long as it is less unprofitable for it to remain in business than to withdraw from the field.) Only in the exceptional conditions in which the quantity demanded at a price determined by cost outruns the ability to produce from existing capacity, does the price lose its connection with cost of production and rise to a point determined by the demand for and limited supply of the specific product, that is, become governed by the direct marginal utility of the product. Even then, the demand and price are usually restrained by the prospect of return to normal conditions in the not too distant future.

In the absence of knowledge of the connection between prices and costs, and on the basis of the prevailing fallacy that the price of each and every product must be determined by the specific demand for and supply of the product—by its own independent marginal utility—contemporary economics is driven to the expectation that without the presence of a vast number of individually insignificant firms, sellers will be in a position to exploit the product’s elasticity of demand. Largely, on this basis, it denounces most branches of industry as “imperfectly competitive,” because they allegedly do not possess a sufficiently large number of sellers to avoid this.

In essence, it is on this basis that it regards big business per se in a way that should be reserved for one or a few firms operating under monopolistic legal protection against competition, but not when operating under the freedom of competition. And then, of course, in the last analysis, it finds that its theory simply does not fit the facts and that it has no applicable theory. Yet it retains the notion that most of the economic world is “imperfectly competitive” and that big business is inherently “monopolistic.”

Pricing Under Patents and Copyrights

Patents and copyrights place the producers who hold them in a position in which they alone decide the quantity of their product that is produced—or at least the quantity of it that is produced by means of their method of production. So long as the patent or copyright lasts, others are simply prevented from producing the good, or, at least, producing it by means of the patent or copyright holder’s method of production.⁶² Nevertheless, as previously explained, patents and copyrights are in no sense a violation of the freedom of competition, but a vital safeguard of it. They protect the intellectual property rights on the basis of which free competition takes place.⁶³ Moreover, in most cases, they do not fundamentally or radically alter the connection of prices with costs of production that has been explained in the preceding pages and in Chapter 6.

What patents and copyrights protect comes under the heading of something new that is more efficient: namely, new, more efficient methods of producing goods that are already being produced and new, more efficient methods of satisfying needs that are already being satisfied in other ways, by different goods. (Of course, patents and copyrights can exist on products and methods of production which do not represent any form of improvement—for example, a copyright on a book no one wants to read or buy, or a patent on a method of production that is more expensive rather than less expensive to use. In such cases, as soon as the fatal flaws are recognized, the patents and copyrights do not protect anything. From that point on, no one seeks to produce such products or use

such methods of production. Nor would anyone do so, if they lacked patent or copyright protection. In this sense, patents and copyrights serve to protect only things which represent improvements, which people would appropriate and put to use if not prevented by the patent or copyright from doing so.)

Insofar as patents and copyrights protect more efficient methods of producing a good that is already being produced, viz., methods of reducing its cost of production, the price of the good is still limited by the cost of producing it by the older, less efficient methods. The patent or copyright merely operates to prevent the price of the good from being reduced immediately to correspond to the lower level of cost made possible by the new method of production.

Ultimately, the price will drop to that point—when the patent or copyright expires—and, most likely, it will drop to some significant extent almost immediately, because the holder will want to take advantage of his lower costs to expand the quantity he sells. But even if the price does not drop at all for the time being, the reinvestment of profits made by virtue of the cost-cutting improvement will operate to increase production and reduce prices somewhere else in the economic system.

As an illustration of this last point, the reinvestment of the profits made by virtue of cutting the cost of producing razor blades, say, in the production of other goods, such as shaving cream and after-shave lotion perhaps, operates to expand the supply and reduce the prices of these other goods. Such a case would be likely to arise in an industry like razor blades, where the demand was highly inelastic and a firm that already accounted for the great bulk of the market would find it unprofitable to cut its price, no matter how substantially it had reduced its cost of production—until it was confronted with the ability of others to produce at the lower cost. What is crucial, of course, is that because of the system of patents and copyrights, the incentive exists to go on developing and introducing improvements in production, and thus for cost of production and price to go on falling in the long run.

If what the patent or copyright protects is an improvement in the methods of satisfying a need that previously had been satisfied by other goods less effectively, then the price of the new good is still limited by the prices and costs of production of the older goods that satisfy the need less effectively. Here, the patent or copyright enables the holder to obtain a premium in the price of his product in comparison with the prices of the older goods serving the same need—a premium that corresponds to the degree of improvement that is perceived as attaching to the use of his product rather than the older products. It is implicit in the nature of such a premium that the

source of the patent or copyright holder's income is the provision of a positive value that the buyers regard as worth more than the premium in price. And thus, once again, there is an immediate gain to the buyers, namely, the extent to which they value the improvement above the premium in price that they pay for it. Eventually, of course, when the patent or copyright expires, the buyers will buy the improved product at no higher price than the original product (except to the extent that its cost of production may be higher), and their gain will be correspondingly greater.

Precisely the newness of patented or copyrighted products typically leads to the practice of setting their prices on the basis of cost of production, though with the addition of a substantially greater-than-usual profit margin. Because patented and copyrighted products are necessarily new, and their potential markets, therefore, largely unknown and undeveloped, the producers of such products more often than not have little or no reliable basis for estimating the elasticity of demand for their products. In such circumstances, it is highly reasonable to price the product in some standard way that is both generous to the producer and yet, at the same time, does not elevate the price too greatly to the buyer, and then attempt to make very high profits by selling the largest possible volume at the price so determined. This is the typical procedure, for example, in the publishing industry, the recording industry, and the motion picture industry, all of which have the perfect legal right to charge whatever price they wish for their unique copyrighted products, but nonetheless appear to follow a defined pricing pattern in which high profits are made not through inordinately high prices, but through high volume at prices that are not all that far above the total cost of production per unit.

Thus, the rewards of innovation that are protected by patents or copyrights typically turn out to be a relatively modest part of the price of the product—perhaps just an additional 10, 20, or 30 percent added to what would constitute a normal profit margin. Financial success comes when this relatively modest additional part of the price is multiplied by a substantial number of units. A very high rate of return on capital then results from the multiplication of the high profit margin by a high capital turnover ratio.

The same principle seems to apply in the pharmaceutical and computer software industries, with the principal difference being that the combination of relatively high costs of research and development and relatively narrow markets often necessitates the charging of much higher prices, in order to cover the resulting high unit costs. In such cases, unexpectedly large quantities demanded, which, of course, serve to reduce unit costs correspondingly, tend to be followed by price reductions, in efforts to reach

wider markets and to forestall potential competition from comparable products and methods of production that could be developed without infringement of the patents or copyrights in question.

In such price reductions, a process takes place in which the proceeds of an extremely high profit margin and rate of profit are reinvested in order to earn a larger amount of profit on the strength of a lower profit margin and rate of profit applied to a greater volume of sales and quantity of capital invested in the production of the good (or more advanced versions of the good). As stated, the existence of such a process also helps to guard against others being tempted to enter into competition through the development of comparable new products or methods of production of their own, which even patent or copyright protection cannot prevent. This last objective, of course, is further secured to the extent that as the result of its reinvestment, the firm is able to achieve reductions in unit costs and improvements in product quality stemming from the adoption of more capital-intensive methods of production. This serves further to increase the capital requirement of any potential competitor and thus further to reduce the likelihood of the actual appearance of such a competitor. The practice of reinvesting a substantial portion of any very high rate of profit in the further production of the extremely profitable product, and then earning a lower rate but larger amount of profit in the production of that good, makes sense for any business. It is the way to transform a temporary bonanza into greater and more lasting success.

In connection with patented life-saving drugs, it is necessary to explain the benevolent role that can be played by the ability to practice price discrimination between classes of buyers with substantially different levels of income. In the case of patented life-saving drugs, every potential buyer whose life depends on the drug can be assumed to be willing, if necessary, to pay his entire life's savings to obtain the drug. Because of this, it may appear that the price of such a drug would necessarily be set at a point at which the marginal buyer at least, would have to pay away his life's savings. If the price were set in this way, then only buyers with income and wealth substantially greater than that of the marginal buyer would be able to avoid paying away their life's savings or something close to it, while all those potential buyers with income and wealth below that of the marginal buyer would simply die for lack of the ability to afford the drug.

Fortunately, where price discrimination can be practiced, it is more profitable for the drug company in such a case both to charge substantially less to the marginal buyer and, at the same time, to offer its product at a

substantially still lower price to the broadest possible class of buyers with wealth and income less than that of the marginal buyer. Indeed, it is entirely possible that no buyer will have to pay away his life's savings, thanks to the existence of a variety of different prices geared to individuals of substantially different wealth and income.

Thus, for example, the full price of a year's supply of the drug might be, say, \$20,000 in money of 1993's buying power. At that price only a small minority of individuals could afford it without being bankrupted. If, however, the drug company can control the distribution of the drug to patients by means of the cooperation of physicians and hospitals, perhaps in conjunction with offering somewhat different versions of the drug, it is in a position to charge such a price only to those who can afford it, while offering a substantially lower price to the broad mass of people who otherwise could not afford it. And it could offer a substantially still lower price to physicians and hospitals who purchased the drug on behalf of charity patients. Where price discrimination is possible, it pays to offer the lower prices to gain access to additional segments of the market. At the same time, the existence of the lower prices for lower-income individuals operates to prevent the price paid by individuals in higher-income segments of the market from approaching the limit set by their marginal valuation of the drug when what is at stake is their very lives.

Today's sometimes outlandishly high price of patented prescription drugs is the result, I believe, of a combination of the existence of a system of collectivized medical costs, and the inability to practice price discrimination.⁶⁴ To the extent that the market for medical care comes to be made up of buyers for whom price is no object, because they are covered by the kind of private medical insurance policies that have prevailed for the last several decades, or by government programs, the price that it is profitable to charge is correspondingly increased. This is because to that extent the higher price does not operate to reduce the quantity of the drug demanded. Thus the incentive is created to charge a higher price. At the same time, various prohibitions against price discrimination serve to prevent the offering of lower prices to those who lack private insurance and are outside of the government programs. Today, if a drug company offered a lower price to anyone, the government and many or most of the private insurance companies would almost certainly demand that they too obtain the benefit of the lower price. (This observation, made with respect to the domestic market of the United States, is confirmed by the recent furor caused by newspaper reports of the availability of lower drug prices in Mexico, a foreign country.) Thus, the offering of a lower price to any segment of the market, at least within the present-day

United States, does not pay. And thus the result is that everyone in the United States is confronted with artificially higher drug prices.

In addition, of course, when discussing today's drug prices, one should not overlook the role that is played in raising drug prices by arbitrary FDA regulations that delay and inhibit the introduction of new drugs. Such regulations are responsible for the average new drug that is introduced having a development cost, and thus price, far in excess of what market conditions require.

Contract Pricing and Radical Privatization

The fact that prices can be set contractually, and thus eliminate all possibility of the exercise of arbitrary power by private individuals in setting their prices, has major bearing on the potential for future privatization. Because of it, it is possible to imagine a day when virtually every good or service but the administration of justice and national defense is provided by unregulated, profit-seeking private businesses.⁶⁵ For example, it is possible to imagine such things as electricity, water, and gas being carried from various points of supply over major trunk lines and various major branch lines, and large individual users, such as major factories or apartment complexes, and associations of small users, such as neighborhood associations of property owners, entering into contracts with the suppliers who offered the best terms. Different suppliers would periodically connect or disconnect their major branch lines with or from local networks of wires and pipeline owned by the large individual users or property owners' associations. Essentially the same principles, of course, apply to sewage lines and to telephone service as well, except that in the case of telephone service, modern technology has or soon will make it possible to connect any two points economically without the use of wires. The ability to transmit to and from a given space satellite either is or soon will be all that is required to link any two locations.

(Despite the rationalizations offered on behalf of the present system of exclusive government franchises and rate controls, or outright government ownership, there is no reason to fear continuous large-scale disruption because of tearing up of streets to lay wire or pipe. Any modern city with five or ten main avenues could, if necessary, easily support five or ten major branch lines of each type running underneath—with just one of each kind per avenue. Any local area parallel to any of these major branch lines could easily be connected just by running a single minor branch line to it from the major branch line, and be disconnected merely by shutting off that minor branch line.)

Property owners and voluntary associations of property owners could obtain fire-protection services on a

contractual basis, after examining competing bids. Such protection would undoubtedly be required by insurers and mortgage lenders, and might even be provided under their auspices.⁶⁶ Private fire fighters could (and should) be authorized to put out fires on the property of individuals who did not subscribe to their services, whenever it appeared to be a matter of life or limb or a danger existed to the property of a subscriber or other requestor of protection. In such cases, it could be made the legal obligation of the property owner(s) in question to pay for the service under a preestablished, publicly known and legally sanctioned set of rates. In cases in which individuals had subscribed to a fire-fighting service, but it was slow to arrive, with the result that it became necessary to use the services of another fire-fighting company, the delinquent fire-fighting service could be legally obliged to pay the bill, plus, perhaps, a preestablished penalty charge. Of course, preestablished cross-billing arrangements would almost certainly exist between fire-fighting companies for cases in which it was necessary for one such service to call upon the assistance of other such services.

Pricing under long-term contract makes it possible to see the day when highways, bridges, and tunnels will be privately owned and operated and supported by tolls, unregulated by the government—even in situations in which only one such road, bridge, or tunnel is feasible. Today, it may be difficult to imagine such an arrangement. This is because one starts in the middle, with a vast population already dependent on the existence of the facility. One then projects the existence of the facility under private ownership, with the owners free to charge whatever tolls they wish. Naturally, in such a situation, the owners would be able to practice a form of extortion against everyone else in the vicinity. But had the facility been private from the beginning, before the area came to be dependent on it, its owners would have had to provide contractual guarantees of permanently reasonable rates *as the precondition* of any subsequent development that would create a dependence on the facility.

In the overwhelming majority of cases, of course, there is more than one route connecting any two points, and very often many routes. Almost always there is the potential for at least several routes and the potential for more routes than currently exist. In such cases unregulated private ownership could probably be adopted even without any provision for long-term contractual guarantees. In perhaps the worst imaginable case, such as a single company somehow being given ownership of all the major bridges and tunnels entering Manhattan Island, the result could not be nearly as serious as the disruption which occurs whenever there is a major transit strike by labor unions. Such a company might charge substantially

higher tolls, which would reduce the flow of traffic in and out of the city through its facilities, but by no means threaten the lifeblood of the city, as does a transit workers' or garbage collectors' strike. Unlike the striking unions, such a company would not be able to resort to physical force to stop competition. And such a company would have competition from the very first, if it set its tolls too high.

Its tolls would be limited not only by the economization on transportation into and out of the city that would take place in response to its higher tolls, but also, from the very first, by the costs of providing ferry service and bringing in more supplies by ship or helicopter. Such competition could begin immediately, if necessary, even if it meant having to use small private boats. But within a very short time, regular large-scale ferry boat service could be in operation if the tolls were high enough to make it attractive. And the same technological expertise which made it possible for the United States Army Corps of Engineers to construct temporary bridges spanning major rivers in Europe in World War II, would make it possible for private enterprise, using improvements in such technology that have been developed since then, to construct substantially better temporary bridges just as fast or faster.

The fact is that New York City and many other major cities are desperately short of transportation facilities as the result of government ownership, with its gross inefficiencies and high costs of construction and maintenance and the policy either of not charging tolls at all or charging tolls that are inadequate in the face of the limited capacity of the facilities. In such a situation, the establishment of private ownership, whether in the hands of just one company or however many companies, might very well be accompanied by a substantial increase in tolls. But this would be followed by a desperately needed increase in the supply of transportation facilities. Within in a few years, permanent new bridges would exist, along with additional tunnels and roadways. Such high tolls as might exist on the present facilities would provide the incentive and, no doubt, to some considerable extent, the means of financing the new facilities, as profits made on the present facilities were reinvested. The net effect would be a radical improvement in the state of transportation and, once the supply of transportation facilities became adequate, tolls that reflected no more than the costs of construction and maintenance plus an allowance for the going rate of profit. At the same time, the costs of construction and maintenance would tend to be the most economical possible and to go on falling in real terms.

Private Streets

Two problems must be discussed in connection with the kind of radical privatization described above. The

first is that of the efficiency of toll collection, especially if private ownership were to be extended to secondary roads and even to city streets. The second is that of the principle of eminent domain, which can be related to almost all of the above areas of privatization.

It would obviously be absurd to stop traffic every block or two in order to collect a toll. A similar problem arises even on major highways, such as the freeways in Southern California, where there is an entrance and exit every one or two miles. Conventional methods of toll collection in such circumstances would be extremely costly as well as time consuming. Fortunately, modern technology is or very soon will be capable of dealing with the problem easily and efficiently. Computer scanning equipment will be capable of reading an automobile's identification at the point of entry and exit from any given body of roadway and thus provide the input for an itemized monthly bill of toll charges. Even so, in the case of residential, neighborhood streets, with little or no through traffic, in which the streets serve merely for people to get to and from major thoroughfares, it may well be found that it is sufficient for local property owners' associations to maintain the streets and finance them by means of dues charged under some form of covenant arrangement among the property owners.

If the owners of thoroughfares also own the property on either side of them (which is a reasonable assumption in the case of city streets or local roads), and seek business from the passing traffic, then their interests would probably be served by the absence of tolls, in order to encourage the passage of traffic by their establishments. Such toll-free thoroughfares would be appropriate for people going shopping. But they will necessarily be relatively slow moving. Toll thoroughfares will be appropriate for through traffic. Here the tolls will limit the traffic and thus make possible more rapid movement. At the same time, they will make the provision of such thoroughfares worthwhile, since the property owners on either side will not be able to gain from the passing traffic itself. The tolls charged on these thoroughfares, of course, will be limited by the fact that slower moving toll-free thoroughfares remain available as an alternative.

Eminent Domain

It is usually taken for granted that the ability to construct roads, railroads, pipelines, and so forth, depends on the existence of the principle of eminent domain, according to which the government has the right to take private property against the will of its owner when its use is necessary for such purposes. The existence of eminent domain is thought to be required in order to prevent a comparative handful of property owners, or even a single individual owner, from arbitrarily and capriciously mak-

ing the construction of such vital facilities either altogether impossible or at least uneconomic, by means of preventing the completion of a route or causing it to take a grossly distorted path.

The principle of eminent domain presents an apparent dilemma. On the one hand, it is presented as a necessary safeguard of the possibility of rational action that depends on the cooperation of large numbers of individuals any one or small number of whom is capable arbitrarily of frustrating all the rest. On the other hand, it appears to constitute a clear violation of the principle of individual rights and thus to have no place in a capitalist society. The apparent dilemma is heightened by the fact that the basis of the existence of individual rights is precisely the provision of safeguards for rational action. Rights protect individuals from the initiation of physical force in order that they can then be free to follow the judgment of their own minds. Moreover, it is necessary to uphold the individual's rights precisely against majorities, and above all against overwhelming majorities.

In an intellectual and cultural environment rational enough to establish a society approaching consistent capitalism, the principle of eminent domain could almost certainly be dispensed with. There would still be irrational, capricious individuals, to be sure, but their number would almost certainly not be great enough to constitute a significant barrier to the accomplishment of any important cooperative venture. Occasionally, perhaps, it might be necessary to have an extra bend in a road, or to make a detour here and there in the course of a pipeline, in deference to the principle of individual rights even when individuals chose to exercise their rights capriciously. Such instances would be minimized not only by the relatively small number of capricious property owners in such a society, but also by the fact that in such a society, rights-of-way for roads, railroads, pipelines, and so forth would be acquired far in advance of the time of actual construction. In the absence of eminent domain, the laying out of such rights-of-way far in advance would be understood to be a precondition for an area's future development. Thus the problem posed by capricious individuals arbitrarily refusing to sell their property or the right of passage through it would be minimized. Communities would be formed with provision for such rights-of-way included in the deeds of the buyers who later might be affected. Where such provision had failed to be made, still, sellers would usually not be asked to part with their property immediately, but only, in effect, to sell an option on its later purchase or use, probably a generation or more in the future. With the necessity of planning long range for the acquisition of rights-of-way, prospective buyers could wait and buy such rights from more reasonable heirs if necessary.

In the present intellectual and cultural state of society, the principle of eminent domain is probably necessary, though not in its present form. One can easily imagine groups of "environmentalists" buying up strips of land in the path of every possible right of way for all kinds of vital roads and pipelines, for no other purpose than to prevent economic development, and succeeding by means of a refusal to sell at any price. A legitimate basis for the principle of eminent domain in such a case can be found in the same source as the legitimate basis for not according full rights to children, or, perhaps closer to the mark, the insane.

Happily, apart from the possible case of the "environmentalists," the far greater part of the seeming dilemma posed by eminent domain could be eliminated as a practical matter even now. All that would be necessary would be the adoption of two very simple measures. The first is to restrict the role of eminent domain to its traditional sphere in the United States, which is precisely such projects as road and pipeline construction, in which a vast stretch of property is required for an indivisible use. (In recent years the principle of eminent domain has come to be extended to the seizing of private property from some owners in order to turn it over to other owners who then employ it in essentially the same way, such as the operation of a department store or the use of the land for residential housing. This is a purely arbitrary redistribution of property, and potentially constitutes a far worse problem than any arbitrary refusal of individuals to sell their property.)

The second necessary measure is to *provide sufficient payment to those whose property is sought*. The overwhelming majority of property owners will be glad to sell if they receive a price for their property that is significantly higher than what they could otherwise obtain for it, and which more than compensates them for any loss of income they may suffer by having to part with it. It is one thing to announce that a road is scheduled to pass through someone's living room, and that his house is to be taken from him at half its actual value. It is something very different if he will be offered two or three times the current value of his house. In the latter case, instead of dreading such economic developments, people would actually vie for the privilege of having their property become the scene of them. This explains the radical difference between people's reactions that presently accompany receiving a letter from the government notifying one of plans to build a road through one's property and, say, a letter from an oil company notifying one that it is likely that one's property contains a petroleum deposit and that the company is interested in drilling wells on it.

This reform, which is immediately practicable, would

remove from the actual operation of the principle of eminent domain almost all of its vicious character. It would reduce the principle to forcing people to take what almost any rational person would be more than glad to take. Thus, the element of actual force would virtually disappear. And this indeed is how the phrase “just compensation” should be interpreted in applying the Fifth Amendment protection of the United States Constitution “nor shall private property be taken for public use without just compensation.”

Such an interpretation would provide a powerful incentive to limit resort to the power of eminent domain and to guarantee that where it was used, the project had major economic value indeed. Furthermore, it should be obvious that the actual limitation of the principle of eminent domain in this way would be much more likely if accompanied by the privatization of the areas in which it was employed. Businessmen are used to paying for what they receive, not taking it, as the government does. And the government is more likely to act as an impartial judge when an outside, private party requests the use of eminent domain, rather than one of its own branches.

Once such a reform had been made, a constitutional amendment could be enacted totally abolishing eminent domain as of, say, fifty years from the date of the amendment’s enactment. This would provide sufficient time to assemble rights of way for all necessary projects thereafter on a strictly voluntary basis.

9. Cartels

Cartels are associations of independent producers of a good who agree to limit their production of it in order to obtain a higher price on the resulting smaller supply. The prevailing belief is that cartels are an evil of capitalism, serving to establish arbitrarily high prices to consumers, and would be a characteristic feature of the economic system in the absence of government intervention to prevent their formation.

The fact is that apart from the handful of cases such as diamonds, in which there are very few physical sources of supply, the only time cartels can succeed under capitalism is when they serve *merely to reduce the extent of losses*, i.e., raise a price from a point of more severe losses to a point of less severe losses or modest profits. This is because, in addition to the problem of deciding which producers must curtail production how much, which is difficult enough in itself (as frequent newspaper reports about the OPEC oil cartel attest), profitable cartels have two further problems, which tend to make their continuation impossible.

There is first the problem of controlling the reinvestment of the profits. If the firms are profitable and want

to reinvest their profits, the industry will expand and the cartel’s price will crash in efforts to find buyers for the additional output. At the same time, the independent reinvestment of the profits may well enable some of the firms to be profitable at the lower prices, while those firms which did not reinvest—or reinvest as much or as skillfully—suffer major losses. In order to prevent the breakdown of the cartel in this way, it would be necessary for the cartel to control its individual members’ reinvestments—something which the mere formation of a cartel is not sufficient to accomplish. Second, and more importantly, a profitable price attracts outside entrants to the field, which not only makes the cartel’s price crash, but also deprives the cartel’s members of volume they could have had. It is the same case we saw in the last section in connection with attempts to produce less in order to sell at a higher price. If the higher price is profitable to outside producers, the effect is that one ends up selling less at a price that is no higher than the costs of such outsiders plus an allowance for the going rate of profit, when one could permanently have sold more at that price.⁶⁷ Furthermore, while it is possible to imagine cartels enjoying a brief period of premium profitability by means of jacking up prices, it should be realized that pricing under contract operates to make even this impossible after it happens once or twice in a field—assuming that it actually does happen.

However, if a cartel exits that is not particularly profitable, these two problems of controlling the reinvestment of profits and attracting the entry of outsiders do not arise, and thus the cartel may succeed. In such a case, there are no significant profits to reinvest and thus there is no problem of having to cut the price to sell an expanded output. And there is nothing to attract outside entrants into the field. In the light of these facts, the following passage from a prominent antitrust textbook should not be surprising: “We even have evidence suggesting that large firms caught engaging in illegal collusion earn *lower* profits than other large firms. Perhaps collusion is most commonly attempted in situations where some adversity has depressed profits below a normal level.”⁶⁸

In such circumstances, it is difficult to see what objection can be made to the formation of a cartel. It is a voluntary association that harms no one and may actually benefit everyone, by virtue of preventing unnecessary losses to producers and thereby enabling them to maintain a level of capacity that will be present to prevent prices from shooting upward when demand for the product revives, as it generally does sooner or later.

As indicated, the one area in which profitable cartels can be formed with a strong likelihood of continued success is in the field of mining, in cases in which the

known, commercially exploitable deposits are few in number. In such cases, the formation of a unified group of producers is a matter of relative ease and, more importantly, the entry of outsiders in response to a higher price is impossible, because the necessary deposits are simply not available to them. The leading examples of this kind are diamonds and mercury.

Even in such cases, it must be kept in mind that the prices that can be charged are still limited by the cost and price of various substitutes, which, however imperfectly, can be used in place of the item for various purposes. For example, man-made diamonds are a substitute for natural diamonds as a cutting tool in many industrial processes. It is even possible that additional deposits of the item exist, which would be capable of commercial exploitation at a sufficiently high level of prices. Quantities of mercury found naturally in sea water are an example. The price charged by the cartel must take such competition or potential competition into account and must be lower than the price that would make significant competition from such quarters profitable.

Moreover, the progressive nature of the economic system under capitalism creates an unremitting downward pressure on the real price charged even by such a cartel. Improvements in the efficiency of producing substitutes and the development of new substitutes, along with the progressive reduction in the real costs of exploiting submarginal deposits, make it necessary for such a cartel to continue to improve its own efficiency of production in order to be able to maintain its profitability in the face of declining real prices for its product. Thus, since the start of the Industrial Revolution, the price of the average diamond, the price of an ounce of mercury, and of almost any other good that a free market would subject to cartelization has substantially fallen generation by generation relative to the income of the average person, along with the fall in the real price of virtually all other goods that have been in existence over the same period of time. Diamond rings and thermometers, for example, have become progressively more affordable. If the producers of the cartelized goods had not improved their efficiency over the decades, their profits would long since have disappeared and they would no longer be in existence, because in that case their customers would have turned to alternative sources of supply that had grown progressively cheaper in real terms. It is as necessary for the diamond or mercury cartel to operate with modern methods of production as it is for producers in any other branch of industry, and to go on improving those methods so long as the producers of substitutes can improve their methods of production, so long as new substitutes can be developed, and so long as the real costs of exploiting submarginal deposits can be reduced.

What is true of the price of such a cartelized good is that at any given time it is higher than would be the case if the same known physical quantity of the good were found in widely scattered deposits. The effect of this higher price is to slow down the rate at which the limited known supplies are consumed. Thus, von Mises is correct in describing the higher prices charged by the cartels as tantamount to a form of conservation.⁶⁹ Only after the fact of improvements in the production of substitutes or in the ability to exploit submarginal deposits is the price (relative to people's incomes) reduced and the rate of consumption increased. Over time, of course, the improvements in methods of extraction introduced by the producers of the cartelized good themselves operate to increase the economically useable supply that their mines provide.

Cartels and Government Intervention

Cartels as an economic problem are the result of government intervention, and where they are formed or maintained on this basis, they represent part of the genuine and very serious problem of monopoly. Three leading instances of such cartels are the largely unacknowledged cartelization of major portions of agriculture in the present-day United States, the OPEC cartel in oil, and the cartels of Imperial Germany before World War I. The U.S. government's enforced restriction of agricultural output for the purpose of reducing its outlays under the farm subsidy program has already been dealt with.⁷⁰ So too has the OPEC cartel and the vital dependence of its success on the policies of the U.S. government, above all, price controls on oil and environmental legislation.⁷¹ Thus, it is only necessary here to deal with the case of the Imperial German cartels.

As von Mises shows in *Human Action*, the German cartels in the decades prior to World War I—the classic case of widespread cartelization of industry—were the result of Bismarck's *Sozialpolitik*. This policy of social security and allegedly prolabor legislation raised production costs in Germany relative to those in other countries, which had not adopted such legislation. In the absence of further measures, the result would have been that German manufacturers could not have sold profitably either at home or abroad. The consequence of that would have been both mass unemployment and the inability to pay for imports of vitally needed foodstuffs and raw materials which could not be produced domestically.

To prevent these consequences, the German government enacted protective tariffs and encouraged the formation of domestic cartels, which could thus sell at high prices in the German market. The extra, monopoly profits thus reaped in the domestic market permitted the subsidization of German exports, which could then be

sold abroad at competitive prices, which were below those at home—a phenomenon described by foreign manufacturers as “dumping.”⁷² (Although von Mises does not mention it, a further necessary aspect of the German government’s policy was an increase in the quantity of money, in order to make possible the larger total expenditure necessary to employ the same number of workers at higher wage rates and to buy the same-sized domestic product at higher prices.) The overall effect of *Sozialpolitik* on the German workers, of course, was that their real, take-home wages were reduced, inasmuch as domestic prices had to rise by enough to cover all the additional costs imposed on employers—the costs not only in the form of higher wage rates, but also in the form of contributions to the social insurance programs.

Thus, it should be clear that the Imperial German cartels were the result of government intervention designed to offset the destructive consequences of prior government intervention. They were not the product of capitalism or the free market.

10. “Monopoly” and the Platonic Competition of Contemporary Economics

After having devoted so many pages to the discussion of the alleged significance of the economic concept of monopoly—ranging from the alleged tendency toward the formation of a single giant firm controlling the entire economic system, on down through the alleged gouging of buyers left and right in this or that particular circumstance, by this or that particular means—it may be found somewhat astonishing that in the hands of contemporary economic theory, the economic concept of monopoly has been absolutely trivialized. Indeed, the substance of the objection that is raised when contemporary economic theory sounds the cry of “monopoly” is actually nothing more than *a condemnation of business for refusing to sustain unnecessary losses*. This fact is not obvious, but it is the unmistakable implication of contemporary economics’ doctrine of “pure and perfect competition.” This doctrine is a central element of contemporary economic theory and is the standard by which it and the Antitrust Division of the Department of Justice decide whether an industry is “competitive” or “monopolistic,” and what should be done about it if they find that it is not “competitive.”⁷³

“Pure and perfect competition” is totally unlike anything one normally means by the term “competition.” Normally, one thinks of competition as denoting a rivalry among producers, in which each producer strives to match or exceed the performance of other producers. This is not what “pure and perfect competition” means. Indeed, the existence of rivalry, of competition as it is

normally understood, is *incompatible* with “pure and perfect competition.” If that is difficult to believe, consider the following passage in a widely used economics textbook: “By way of contrast, intense rivalry may exist between two automobile agencies or between two filling stations in the same city. One seller’s actions influence the market of the other; consequently, pure competition does not exist in this case.”⁷⁴

While competition as normally, and properly, understood rests on a base of individualism, the base of “pure and perfect competition” is collectivism. Competition, properly so-called, rests on the activity of separate, independent individuals who own and exchange private property in the pursuit of their self-interest. It arises when two or more such individuals become rivals for the same trade. The concept of “pure and perfect competition,” however, proceeds from an ideology that obliterates the existence of individuals, of private property, and of exchange. It is the product of an approach to economics based on what has aptly been characterized as the “tribal premise,” viz., the collectivist view that the individual human being is a cell in a greater organism: Mankind, the State, the Nation, or the Tribe.⁷⁵

The tribal premise dominates contemporary economic theory, and is accepted not only by the enemies of capitalism, but even by its supporters. The link between the concept of “pure and perfect competition” and the tribal concept of man, is a tribal concept of property, of price, and of cost.

According to contemporary economics, no property is to be regarded as really private. At most, property is supposedly held in trusteeship for its alleged true owner, “society” or the “consumers.” “Society,” it is alleged, has a right to the property of every producer and suffers him to continue as owner only so long as “society” receives what it or its professorial spokesmen consider to be the maximum possible benefit. As another supporter of the “pure-and-perfect-competition” doctrine declares in his textbook: “At any point in time a society possesses a pool of resources either individually or collectively owned, depending upon the political organization of the society in question. From a social point of view the objective of economic activity is to get as much as possible from this existing pool of resources.”⁷⁶

According to the tribal concept of property, “society” has a right to 100 percent of every seller’s inventory and to the benefit of 100 percent use of his plant and equipment. The exercise of this alleged right is to be limited only by the consideration of “society’s” alleged alternative needs. Thus, a producer should retain some portion of his inventory only if it will serve a greater need of “society” in the future than in the present. He should produce at less than 100 percent of capacity only to the

extent that “society’s” labor, materials and fuel, which he would require, are held to be more urgently needed in another line of production.

The ideal of contemporary economics—advanced half as an imaginary construct and half as a description of reality, with no way of distinguishing between the two—is the contradictory notion of a private-enterprise, capitalist economy in which producers would act just as a socialist dictator would wish them to act, but without having to be forced to do so.⁷⁷ In accordance with this “ideal,” contemporary economics tears the concepts of price and cost from the context of individuals engaged in the free exchange of private property, and twists them to fit the perspective of a socialist dictator. It views the system of prices and costs as the means by which producers in a capitalist economy can be led to provide “society” with the optimum use and “allocation” of its “resources.”

A price is viewed not as the payment received by a seller in the free exchange of his private property, but as a means of *rationing* his products among those members of “society” or the “sovereign consumers” who happen to desire them. Prices are justified on the grounds that they are a means of rationing, superior to the issuance of coupons and priorities by the government. Indeed, rationing itself has been described by Nobel Laureate George Stigler as “non-price rationing,” prices allegedly being the form of rationing that exists under capitalism.⁷⁸

Similarly, a cost, according to contemporary economics, is not an outlay of money made by a buyer to obtain goods or services through free exchange, but the value of the most important alternative goods or services “society” must *forgo* by virtue of obtaining any particular good or service. A typical textbook formulation is:

The social cost of using a bundle of resources to produce a unit of commodity *X* is the number of units of commodity *Y* that must be sacrificed in the process. Resources are used to produce both *X* and *Y* (and all other commodities). Those resources used in *X* production cannot be used to produce *Y* or any other commodity. To illustrate with a simple example, think of Robinson Crusoe living alone on an island and sustaining himself by fishing and gathering coconuts. The cost to Crusoe of an additional fish is measured by the number of coconuts he has to forgo because he spends more time fishing.⁷⁹

On the basis of this concept of cost, contemporary economics holds that the only relevant cost of production is “*marginal cost*.” As a rule, and roughly speaking, for the concept can only be approximated, “marginal cost” is held to be the cost of the labor, materials, and fuel required to produce an additional unit of a product. Their value is supposed to represent the value of the most important alternative goods or services that “society” forgoes in obtaining this additional unit.⁸⁰ (Marginal cost

depends on the context. It is always the *extra* cost that must be incurred from a given, present starting point, and varies with this starting point. For example, the extra cost of producing an automobile is typically the cost of labor, materials, and fuel, because normally one may take for granted the existence of the automobile factory and its equipment. But if the production of an additional automobile requires an additional automobile factory, then, in that context, the marginal cost of an automobile would include the whole cost of the factory as well. By the same token, if the automobile has already been produced and is sitting in the auto company’s lot, the marginal cost becomes merely the cost of shipping it. If it has already been shipped to a dealer and is in his lot, the marginal cost is hardly anything at all.)

It must be stressed that the concept of “marginal cost” normally *excludes* the cost of existing factories and machines. The reason for this exclusion is that these assets are “here,” they were paid for in the past and, therefore, their cost does not constitute an additional cost from the present moment forward. Accordingly, their cost is not regarded as a concern of “society” in the present.

Marginal cost is supposed to be the measure of the value of alternative goods forgone, because the prices of the factors of production that remain to be purchased and which constitute marginal cost are supposed to be determined by the value of the alternative goods whose production must be forgone. For example, the prices (wages) of the labor, materials, and fuel required to produce and ship an additional automobile are supposedly determined by the value of the refrigerators, television sets, or whatever other goods cannot now be produced because the factors of production required to produce them will be used to produce an additional automobile instead.⁸¹

All prices, according to this collectivist, tribal view, should be *scarcity prices*, that is, prices determined by the necessity of balancing a limited supply against a comparatively unlimited demand.

Supply, in the context of this doctrine, means the goods that are *here*—in the possession of sellers—and the potential goods that the sellers would produce with their existing plant and equipment, if they considered no limitation to their production but “marginal cost.” *Demand* means the set of quantities of the goods that buyers will take at varying prices. Every price is supposed to be determined at whatever point is required to give the buyers the full supply in this sense and to limit their demand to the size of the supply.

The essence of this theory of prices is the idea that every seller’s goods and the use of his plant and equipment belong to “society” and should be free of charge to “society’s” members unless and until a price is required to “ration” them. Prior to that point, they are held to be

free goods, like air and sunlight; and any value they do have is held to be the result of an “artificial, monopolistic restriction of supply”—of a deliberate, vicious withholding of goods from “society” by their private custodians. After that point, however, the value they may attain is limited only by the importance that buyers attach to them.

On this view, every price is supposed to be an index of the intensity of “society’s” need or desire for a good—an index of the good’s “marginal social utility.” Production should be carried to the point of price equals marginal cost, it is argued, because only then is production at an optimum. So long as price is greater than marginal cost, it is claimed, “society” is in a position to obtain a good that it values more at the expense of other goods that it values less. For the price of the good is held to be the measure of its value, while the marginal cost is allegedly the measure of the value of the alternative goods that must be forgone in order to make the factors of production available for an expanded production of the good in question. By the same token, if the price of the good is less than its marginal cost, then “society” would supposedly gain by curtailing the production of the good in question and expanding the production of other goods that employ the same factors of production.

In the words of Samuelson and Nordhaus: “Only when prices of goods are equal to marginal costs is the economy squeezing from its scarce resources and limited technical knowledge the maximum of outputs.”⁸² “Price,” they declare, in the previous edition of their textbook, “is the signal that consumers use to indicate how much they value various goods. Costs, and particularly marginal costs, are the indicators of how much of society’s valuable resources each good’s production utilizes: scarce land, sweaty labor, and other resources that could produce other goods.”⁸³

But, despite all this, what does the “imperfect competitor”—viz., the “monopolist,” the “oligopolist,” or the “monopolistic competitor”—do, according to Samuelson and Nordhaus?

Does it produce goods up to the point where their social cost—as measured by *MC* [Marginal Cost]—is equal to what the last unit of the good is worth to society—as measured by market *P* [Price] resulting from consumer money votes? No. The imperfect competitor is contriving to keep its output a little scarce. It is contriving to keep *P* above *MC* because in that way it sets $MR = MC$ [Marginal Revenue equal Marginal Cost] and thereby maximizes its profit. So society does not get quite as much of *A*’s [the “imperfect competitor’s”] good as it really wants in terms of what that good really costs society to produce.⁸⁴

The following series of examples will help to illustrate the alleged crime of the “imperfect competitor.”

We can begin by imagining a simple fishing village.

The fishing fleet goes out and returns with an enormously successful catch. The catch is so large that it exceeds the ability of the local canning and freezing plants to process it and the local human and cat population to consume it before it spoils. In these circumstances, the rationing theory of prices holds that fish are a free good; they are not scarce; their marginal social utility is zero. Hence, no just basis exists for a price being charged for fish; they should be given away for nothing.

The fishermen, we can be sure, have a different view of things. They face ruin with a price of fish that is too far below their costs, let alone zero. (And, incidentally, if the fishermen are ruined, the long-run effect will be a smaller-sized fishing fleet, a smaller long-run average catch of fish, and a higher long-run average price of fish to the buyers.) If the fishermen can come to an understanding among themselves, they will throw back part of their catch in order to make the remaining supply command a positive price that is not too far below their costs or is modestly above their costs. If they succeed in doing so, however, the tribal-rationing theory denounces them for a “monopolistic restriction of supply.”

Exactly the same type of crime is held to be committed every time an inventor, or any other intellectual creator, earns something by virtue of the ideas he has created—indeed, so much as covers any part of the costs he has incurred in developing his work. As von Mises points out, the ability of ideas—of formulas, recipes, and techniques of all kinds—to render service is potentially unlimited.⁸⁵ The only physical limit to their ability to render service at any given time is the availability of the physical factors of production. On this basis, the rationing theory of prices must view ideas as inherently *free goods* and the existence of any prices being charged for their use as the result of a “monopolistic restriction of supply.”

This conclusion follows because if the physical factors of production are available in any desired quantity to produce more of a product, in accordance with a given idea, then the supply of the product can be increased and its price will fall. This can continue until the price falls all the way to the point that it covers only the cost of the physical factors of production together with the going rate of profit on the capital invested in the physical factors of production. If the lack of the necessary physical factors of production is what limits the production of a product, then the price of the limiting physical factor or factors of production will rise to reflect the high price of the product. Either way, nothing will remain for the service rendered by the idea.

If and to the extent that something does remain for the use of the idea, it is held to be the result of an “artificial scarcity” having been created in the use of the idea. The owner of the idea, whether it is patented, copyrighted, or

is a trade secret, restricts its use below the limit set by the availability of the physical factors of production, in order to secure a price for the use of his idea (or an allowance for the use of his idea in the price of the product it serves to produce). In effect, like the fishermen who throw back some fish, he holds down the number of times his idea is used in order to secure a price on the use of it that he does allow.⁸⁶

Finally, and, for present purposes, most importantly, the same kind of crime is held to take place in connection with the use of existing plant and equipment. According to the tribal-rationing theory, fixed costs, notably, the depreciation cost of plant and equipment and interest paid on capital invested in plant and equipment, are only properly recoverable as and when the use of the plant and equipment becomes "scarce." Any allowance in the price of the product for fixed costs, other than in the case of the use of the plant and equipment being "scarce," is also supposed to rest on a "monopolistic withholding of supply."

This notion can be illustrated by assuming the existence of plant and equipment with some definite capacity to produce—for example, the capacity to produce one million units of product per month. This capacity to produce can be construed as representing a supply of one million service-units of plant and equipment. If the quantity demanded of the product that the plant and equipment helps to produce is less than a million units a month at any price greater than the marginal cost of a unit, then, according to the tribal-rationing doctrine, no just basis exists for any allowance for plant and equipment being charged in the price of the product. This is shown in Table 10–2, where it is assumed that marginal cost is constant at \$8 per unit and that, even at a selling price as low as \$8 per unit, the quantity demanded of the product is less than a million units.

Under the assumptions made in Table 10–2, if the product were to be sold at a price of \$10, the quantity of the product demanded would be only 500,000 units. If

the owners of the plant and equipment kept the price at \$10 and went on supplying only 500,000 units, then they would be in the position of receiving an allowance of \$2 in the price of the product for a service-unit of plant and equipment (viz., the product's selling price of \$10 minus the marginal cost of \$8). This, it is held, would be "inefficient"—viz., unjust, according to the perspective of collectivism. With a supply of 1 million service-units of plant and equipment and a requirement for only 500,000 such service-units, there is no scarcity of service-units to justify such a price, it is held. Efficiency and justice, it is claimed, demand that the implied allowance for a service-unit of plant and equipment be reduced.

Now this will be accomplished if the price of the product is cut from \$10 to \$9. But, as Table 10–2 shows, even at a price of \$9, the quantity of the product demanded, and thus the number of service-units of plant and equipment required, grows only to 600,000. The service-units of plant and equipment are still not scarce. Even if the selling price of the product is reduced all the way to \$8—the marginal cost—and the implied allowance for plant and equipment is correspondingly reduced all the way to zero, the quantity of the product demanded—and thus the quantity of service-units of plant and equipment required—still grows only to 700,000. Thus, the tribal-rationing theory concludes, plant and equipment in this case simply are not scarce and therefore deserve no allowance in the price of the product.

Such an allowance would be deserved only if at a price above \$8, the quantity demanded of the product, and thus the requirement for service-units of the plant and equipment, were greater than a million units. In that case, the plant and equipment's service-units would be scarce and deserve an allowance in the product's price. The allowance would be necessary to reduce the quantity of the product demanded to a million units. Such an allowance could be anything, it is implied. It need have no fixed limit. It would be whatever is required to reduce the

Table 10–2

The Implications of Price Equal Marginal Cost for the Recovery of Fixed Costs

Quantity of Product Supplied and Demanded	Price	Marginal Cost	Implied Allowance in Product Price for Use of Plant and Equipment
500,000	\$10	\$8	\$2
600,000	\$9	\$8	\$1
700,000	\$8	\$8	\$0

quantity of the product demand to equality with the limited capacity available to produce it. Thus, if at a price of \$8, 5 million units of the product were demanded and a corresponding requirement for 5 million service-units of plant and equipment existed, and it took a price of \$50 to reduce the quantity of the product demanded—and the requirement for service-units of plant and equipment—to a million units, that supposedly would be perfectly acceptable. (In actual practice, of course, one may be certain that most proponents of the doctrine would soon be crying for price controls, if the selling price came to exceed the full costs by any substantial amount.)

As stated, in all circumstances in which the owners of plant and equipment recover any part of their investment, short of the services of their plant and equipment being in a state of scarcity, they are accused—just like the fishermen and the owners of intellectual creations—of monopolistically withholding a part of their supply from the market in order to obtain a price on the portion they do allow to enter the market. Automobile plants, steel mills, and all other lines of business which are able to recover their fixed costs at less than capacity operation, are denounced for monopolistic restrictions of supply. This is the implicit substance of all the attacks made against “oligopoly” and the alleged refusal of “oligopolists” to cut prices in the face of a decline in demand. (Similarly, the attacks made against “monopolistic competition” can be understood as attacks on the ability to profit from a “contrived scarcity” of the services of intellectual creations, such as a product’s distinctive features and its brand name.)

Proponents of the tribal-rationing theory may not agree with my claim that their doctrine calls for no recovery of fixed costs short of capacity operation. They almost always assume that marginal cost continuously rises, starting from a very low percentage of capacity operation, and that in the relevant range of operations, it already exceeds average variable cost.⁸⁷ (Average variable cost can be understood as the average cost per unit on account of labor, materials, and fuel.) On these assumptions, an equality of price with marginal cost is compatible with some or even full recovery of fixed costs, short of the point of 100 percent capacity operation of the whole firm or even single factory. For in this case, when price is equal to marginal cost, it is equal to the marginal cost only of the present marginal unit; it simultaneously exceeds the lower marginal costs of all the earlier units. Out of that excess can come coverage of fixed costs.

Unfortunately for the proponents of the tribal-rationing theory, marginal cost does not continuously rise. The law of diminishing returns, which is the basis presented for the assumption that it does, is not in fact an adequate

basis for such a conclusion.⁸⁸ The law of diminishing returns implies merely that *at some point* more plant and equipment is required if the output per unit of labor and other variable factors of production is not to decline.⁸⁹ It is entirely consistent with the law of diminishing returns that prior to full capacity operation of a plant, or a level of operation not far short of full capacity operation, marginal cost is constant. Indeed, this is the typical case in manufacturing and processing. To confirm this conclusion, one need only imagine a dress factory, say, with rows of workbenches and sewing machines. So long as there are empty workbenches and idle sewing machines, there is no reason for assuming that the employment of additional labor, and the use of additional materials and fuel, will be accompanied by diminishing returns.

A reasonable basis for assuming a rise in marginal cost as output levels increased would be if the firm owned machinery (or whole factories) of different ages, representing earlier and later models, and thus of marked differences in efficiency. It might be imagined that, say, 20 percent of its capacity was in the form of the newest and most efficient machines, which enjoyed the lowest marginal cost per unit; that a further 60 percent of its capacity was in the form of somewhat older and less efficient machines, which necessitated production at a higher marginal cost; and that its final 20 percent of capacity was in the form of still older, still less efficient machines, which necessitated production at a still higher level of marginal cost. Similarly, it might well be the case that the addition of a third shift would entail a higher level of marginal costs, because of the need to pay a somewhat higher level of wages in off hours. But none of these cases implies continuously rising marginal cost. They imply a marginal cost that rises in two or three steps and at each step stays constant over the range of that step.

In such conditions, the only modification or, more correctly, elaboration, that needs to be made to the statement that the rationing theory of prices requires the achievement of capacity operation before fixed costs can justly begin to be covered is that capacity operation must be achieved *for the particular grade of capacity concerned*. For example, in order for the fixed costs on the most efficient 20 percent of our dress company’s machinery to justly begin to be covered, according to the rationing theory of prices, that factory must be operating at a level equal to at least 20 percent of capacity. If it is, the service-units representing that grade of capacity are in a state of scarcity. By the same token, the only way that fixed costs on the machines representing the next 60 percent of capacity can justly begin to be covered, according to the rationing theory of prices, is if the factory is operating at a level equal to at least 80 percent of its capacity. At that point, the service-units representing this

grade of capacity are in a state of scarcity.

It thus turns out, upon analysis, that the tribal-rationing theory can be understood as an attempt to apply the Ricardian land-rent doctrine to the determination of the value of the services of plant and equipment. It should be recalled that according to Ricardo, rent commences on land of the first quality only when all of it is under cultivation and it becomes necessary to resort to the cultivation of land of the second quality, and that rent commences on land of the second quality (and correspondingly increases on land of the first quality) when all of it, in turn, comes under cultivation and it becomes necessary to resort to land of the third quality.⁹⁰

The essential point remains that compensation for produced capital goods is being made to depend on an absolute scarcity of their services and that any attempt by their owners to obtain compensation short of such a scarcity is denounced as a monopolistic restriction of supply. In our example of the dress factory, which certainly represents a typical case when modified to have three grades of capacity, the tribal-rationing theory holds that efficiency and justice demand that the firm earn nothing toward the replacement of the great bulk of its machinery whenever it operates below 80 percent of capacity. (And to earn anything toward the replacement of the factory itself, it would probably have to operate at a full 100 percent of capacity—unless it were fortunate enough short of that point to have some machinery in operation of such inefficiency that “rents” on its more efficient capacity were high enough to leave something over for the replacement of the plant itself.) If despite the absence of these conditions the firm does earn something on the bulk of its capacity, it is denounced for monopolistically restricting the services of its plant and equipment and the supply of its products.

The Doctrine of Pure and Perfect Competition

To understand the view of competition held by contemporary economics, all one need do is take such alleged monopolistically contrived scarcities as those just described, as the standard of the kind of evil that competition is supposed to prevent. If one follows this procedure, one can grasp the nature of “pure and perfect competition” and how it is a product of the tribal view of property, of price, and of cost.

Competition in contemporary economics is viewed as the means by which prices are driven down either to equality with “marginal cost” or to the point where they exceed “marginal cost” only by whatever premium is necessary to “ration” the benefit of plant and equipment operating at full capacity.

This is not competition as it exists in reality. The competition which takes place under capitalism acts to

regulate prices simply in accordance with the full costs of production and with the requirements of earning a rate of profit. It does not act to drive prices to the level of “marginal costs” or to the point where they reflect a “scarcity” of capacity. The kind of “competition” required to do *that*, is of a very special type. Literally, it is out of this world. It is “pure” and “perfect.”

No one has ever defined “pure and perfect competition”—the procedure is merely to present a list of conditions which it requires. A fairly full list of these conditions is presented by Professor Clair Wilcox (who is not an advocate of capitalism) as if it were a definition of “pure and perfect competition.” He writes:

The requirements of perfect competition are five: First, the commodity dealt in must be supplied in quantity and each unit must be so like every other unit that buyers can shift quickly from one seller to another in order to obtain the advantage of a lower price. Second, the market in which the commodity is bought and sold must be well organized, trading must be continuous, and traders must be so well-informed that every unit sold at the same time will sell at the same price. Third, sellers must be numerous, each seller must be small, and the quantity supplied by any one of them must be so insignificant a part of the total supply that no increase or decrease in his output can appreciably affect the market price . . . Fourth, there must be no restraint upon the independence of any seller or buyer, either by custom, contract, collusion, the fear of reprisals by competitors or the imposition of public control. Each one must be free to act in his own interest without regard for the interests of any of the others. Fifth, the market price, uniform at any instant of time, must be flexible over a period of time, constantly rising and falling in response to the changing conditions of supply and demand. There must be no friction to impede the movement of capital from industry to industry, from product to product or from firm to firm; investment must be speedily withdrawn from unsuccessful undertakings and transferred to those that promise a profit. There must be no barrier to entrance into the market; access must be granted to all sellers and all buyers at home and abroad. Finally, there must be no obstacle to elimination from the market; bankruptcy must be permitted to destroy those who lack the strength to survive.⁹¹

To summarize these conditions: uniform products offered by all the sellers in the same industry, perfect knowledge, quantitative insignificance of each seller, no fear of retaliation by competitors in response to one’s actions, constant changes in price, and perfect ease of investment and disinvestment.

To understand the alleged need for all these conditions and what they would mean in reality, it is necessary to project them on a concrete example. This is usually not done at all, and is never done fully—if it were, neither the theory of “pure and perfect competition” nor the rationing theory of prices could be propounded. So I shall use an example of my own, which will not be of a kind

used by their supporters, but which will express accurately the meaning of these theories.

Imagine a movie theater with 500 seats. The picture is about to go on; the projectionist, the ushers and the cashier are all in their places. "Society" has the alleged right to the occupancy of 500 seats. If they are not all occupied for this performance, no future satisfaction can be obtained by any storing up of the use of the seats for a future time. The seats, the theater, the film, the necessary workers are "here." "Society," supposedly, "has them" and now it demands the full benefit from its alleged property.

If the film is not run, the only thing that "society" can save is the electric current which might be made available elsewhere, or the coal which must be consumed to generate the current. The costs of the theater, the film, the workers are all "sunk costs"—"water over the dam," as the textbooks say—and, since "bygones are bygones," the only thing which counts for "society" now is the cost of the electric current.

The theater, according to the tribal-rationing theory, should charge an admission price which will guarantee the sale of 500 tickets for the performance. If droves of people are standing in line for admission, it should raise the price to whatever point is required so that only 500 people will be able to afford it. If all the people in line have identical incomes, the same medical disabilities, and natures of equal sensitivity, such a price, supposedly, will mean that the 500 people who want to see the film most, will see it. If they are unequal in these respects, that is already supposed to be an "imperfection" in the justice of the "market mechanism."

If, however, there are few people standing in line, the theater should begin reducing its admission price. It must keep on reducing its admission price until it has attracted 500 customers. If an admission price of only 2¢ is required to get this many customers, then, supposedly, that is what should be charged, provided only that the revenue brought in at the box office covers the cost of the electric current.

If the theater persists in charging its standard price of, say, \$5, at which it sells less than 500 tickets, then, according to the tribal-rationing doctrine, it is guilty of "administering" its price and, of course, of "monopolistic restriction of supply." It is engaged in a process of "price control"—in violation of the "laws of supply and demand"—and in creating an "artificial scarcity" of seats by "monopolistically" withholding a portion of its supply from the market to maintain a high price on those seats for which it does sell tickets.

If the theater cannot sell 500 tickets even at 1¢ per ticket, then, according to this theory, it must either open its doors for free or cancel the performance. In this case,

a theater seat is, allegedly, a free good—it is no longer "scarce" in relation to the demand for it, and so there is no longer any need for a price because there is no longer any need to ration theater seats. If there are 100 people who want to see the movie and who are prepared to make it worth the theater owner's while, he should perhaps run the film—contemporary economics would hold—provided he sells the remaining 400 tickets at whatever price is required to unload them, including zero. This, however, would be another "imperfection" in the "market mechanism"—*price discrimination*. The "ideal solution" in such a case, it is alleged, would be to have the government nationalize the theater, charge nothing and subsidize the loss.⁹²

In the process of adjusting its price to attract customers, the theater must not, of course, send anyone out in the street to tell people about the movie it is playing or the price it is charging. That would be another "imperfection"—advertising. Advertising, according to this theory, is a wasteful and vicious means of "demand creation"—it makes the "consumers" act differently than they really want to act. So, as the theater is reducing its price, it must be careful not to be too obvious about it. Simply changing the price in the cashier's window should be enough.

However, while advertising by the theater is an "imperfection," "perfection" requires that all potential customers of the theater possess perfect and instantaneous knowledge of its price changes and of the picture it is showing. It is another "imperfection" in the operation of the "market mechanism" if people about to enter other theaters, or riding in their automobiles, or making love, do not receive instantaneous communication of the price changes, so that they may speedily alter their plans. And, presumably, it is an "imperfection" if they have not already seen all the movies many, many times—to be perfectly informed about them.

Because the theater owner wants to "maximize his profits," he will not act in accordance with the theory's tribalistic precepts. However, he *would*, it is argued, if knowledge *were* perfect and automatic, if people *did* race back and forth between theaters in response to penny price differences, and if a number of further conditions were also fulfilled. If, for example, there were 401 identical theaters in the same neighborhood, all showing the same movie, and all in the same position with regard to empty seats, then, it is argued, the cunningly clever, "profit-maximizing" businessman would reason as follows: "At my standard price of \$5, I can sell only 100 tickets today. But if I charge \$4.99999 . . . 9 (it is a standard assumption of the theory that all economic phenomena are mathematically continuous and thus capable of treatment by calculus), I can sell all 500 tickets. For in response to this insignificant price change, which

is infinitely close to my present price, I could attract away one customer from each of the 400 other theaters. This would be very good for me, and none of the other theater owners would really notice the loss of just one customer, and thus no one would match my lower price. So that is what I will do.”

The same thought, however, will be racing simultaneously, it is assumed, through the heads of the other 400 theater owners, and so everyone’s price will be trimmed just so much, and no one will end up with any additional customers drawn from other theaters. Each theater may attract *one percent* of an additional customer who otherwise would not have gone to the movies, but that is all.

The same process is repeated at the infinitesimally lower price, as each theater owner seeks to “maximize his profit,” led by the idea that his insignificant price change will draw an unnoticed amount of business from each of many competitors, who will not reduce their prices in response to *his action*. This process of infinitely small price reductions is supposedly performed with infinite rapidity—presumably through the “automatic market mechanism”—and so, instantaneously, the price is brought down to the point where everyone’s theater either is jammed to capacity or must close its doors.

According to the theory of “pure and perfect competition,” the large number of sellers is the main condition required to drive prices either to “marginal cost” or to the point where they reflect a “scarcity” of the capacity that is “here.” If the individual seller were a significant part of the market and were in a position to handle a major part of the business done by his competitors, then, supposedly, he would never cut his price because he would know that as a result of *his action* others will lose so much business that they will have to match his cut and that he will thus be left basically only with the lower price. When there are a large number of small sellers, every price cut is also matched, but, the argument is, *not because of one’s own price reduction*, but because the other sellers are led to cut their prices independently, guided by exactly the same thought.

The significance of all sellers having an *identical* product is supposed to lie in the greater responsiveness of customers to price changes. If each theater is playing a different movie, customers are not likely to shift their business among the various theaters in response to infinitesimal price differences, and so a theater owner will have less incentive to trim his price. The significance attached to perfect knowledge is similar.

This portrait of the economic world of perfection is not yet complete, however. There remain two other major requirements if “society” is to derive the maximum benefit from its “scarce resources.” It must be possible, as Professor Wilcox puts it, for investment to “be speedily

withdrawn from unsuccessful undertakings and transferred to those that promise a profit. There must be no barrier to entrance into the market . . .” This condition would be achieved if movies were shown in tents, with projectors using candle light instead of electricity. Then, whenever demand changed, theater owners would merely have to unfold or fold up their theaters, and light or blow out their candles.

This would be “perfection,” but not quite in its full “purity.” For in addition, “the market price,” as Professor Wilcox says, “uniform at any instant of time, must be flexible over a period of time, constantly rising and falling in response to the changing conditions of supply and demand.” This would be achieved if, after leaving the theater and going to a restaurant for dinner, one were not given a menu, but were seated in front of a ticker tape—and were offered a futures contract on dessert; and if afterward, on leaving the restaurant and walking back to one’s apartment, one would not know whether one could afford to live there that night, or whether the rentals of penthouses had collapsed. Only then would the world be “purely perfect.”

Implications of Marginal-Cost Pricing

It should be obvious that the “purely perfect” world of pure and perfect competition would be an utter chaos. If prices had to constantly be set equal to marginal cost, not only would firms routinely be prevented from charging prices high enough to cover their fixed costs, but many firms would routinely be prevented from charging *any price at all!* Consider how many cases there are like movie theaters. Consider how often not only movie theaters, but also athletic stadiums, concert halls, and opera houses have empty seats. Consider how often airplanes, trains, and buses travel with empty seats. What is the marginal cost of admitting or carrying one more customer in these cases? What is the marginal cost of providing electricity or telephone service? What is the marginal cost of using any invention one more time? A price equal to marginal cost in any of these cases would have to be zero or not very far above zero.

The supporters of the pure-and-perfect-competition doctrine may or may not be aware of the frequency with which their doctrine calls for a price of zero or almost zero, but they are prepared to deal with such cases. According to Samuelson and Nordhaus, in their treatment of “ideally regulated pricing” in connection with public utilities:

If $P = MC$ [price = marginal cost] is such a good thing, why shouldn’t the regulators go all the way and make the monopolist lower P until it is at the intersection point of the DD [demand] and MC curves [viz., where price equals marginal cost] . . . ?

Actually, requiring $P = MC$ or *marginal-cost pricing* is the ideal target for economic efficiency. But one serious problem arises. A firm that has declining cost and produces where price equals marginal cost, will be incurring a chronic loss. . . .

Firms of course will not operate for long when they are running at a loss. Hence the ideal regulatory solution requires the government to subsidize the decreasing-cost producer, presumably by funneling tax revenues to the firm.⁹³

Thus, in the view of Samuelson and Nordhaus, and of the so-called mainstream of contemporary economics that they represent, in cases in which marginal-cost pricing entails a chronic loss, it is still the ideal; the loss should be supported by a permanent government subsidy. This is in the name of “economic efficiency”—efficiency by the absurd standard that all that counts for efficiency is providing “society” with something it allegedly values more at the expense of something it allegedly values less, irrespective of who is sacrificed, of what coercion is involved to provide the taxes to cover the losses, of the notorious inefficiencies of government subsidies (and government ownership), and irrespective of the utter short-sightedness of using marginal cost as the criterion and assuming that anyone could be benefited by a policy that makes it impossible for an economic activity to sustain itself.

In the allegedly ideal world of price having to be set equal to marginal cost, there would be a radical reduction of productive capacity relative to the supply of labor and materials, and an even more radical reduction in capacity in cases in which marginal cost is zero or close to zero. In such a world, of course, there could be virtually no private research and development whatever, because of the zero marginal cost of using the results of research and development and thus the alleged obligation to charge nothing for its use. (Presumably, according to Professors Samuelson and Nordhaus, the government would conduct all research and development on the basis of tax revenues—in the name of “efficiency.”) As for fixed productive capacity of any kind, after a series of losses, its supply would be cut back to the point where whatever capacity remained would be operated at 100 percent often enough so that it could be replaced. At those times, the price of the product or service would be high enough and the profits great enough to compensate for the losses incurred when having to sell at marginal cost.

This would be a world largely incapable of making adjustments to changes in demand through changes in supply. To the degree that less capacity existed, increases in demand would more quickly run up against a physical inability to expand supply. Such a world would be full of major production bottlenecks. In such a world, the government would actually lack the power to provide any

substantial subsidies—it would be impoverished along with the citizens who had to support it.

To term such a world “economically efficient,” as such writers as Samuelson and Nordhaus repeatedly do, is to adopt a standard of efficiency by which the economy of Soviet Russia was more efficient than that of the United States. In Soviet Russia, of course, there was less of everything than in the United States, but what there was, was used more fully. In Soviet Russia, the citizen wore his single suit everyday (assuming he was rich enough to own a suit). In the United States, the citizen has long had the idle capacity of several suits. Just so, with regard to plant and equipment. Under capitalism, the normal state of production requires the possession of extra machines and plant capacity in every industry, to meet every foreseeable change in demand. This is not a “waste,” not any more than the fact that the consumers under capitalism own more clothes than the ones they happen to be wearing. But such a desirable state of affairs would not be possible if producers had to sell at prices equal to marginal cost whenever they operated short of the full capacity of the plant and equipment concerned.

Ironically, what the “pure-and-perfect-competition” doctrine seeks is *the abolition of competition among producers*. Its “ideal” is a state in which producers are unable to take business away from other producers. If a producer is operating at full capacity, he cannot meet the demand of a single additional buyer, let alone compete for that demand. He cannot compete for additional business if he is operating merely at the full capacity of a given grade of plant and equipment and his idle capacity is of a kind whose operating cost is greater than the currently prevailing price. And if he is not producing at full capacity even of a given grade of plant and equipment and is charging a price equal to his “marginal cost,” he still cannot compete for the business of any additional buyers because he is forbidden to “differentiate” his product or to advertise it. Thus, the normal competition of capitalism—the competition of producers for customers, based on an ability to expand production—would give way to a competition of consumers for meager, essentially fixed supplies of goods, in which the only way anyone could have more of a good would be by virtue of someone else having less of it. The only relief from this state of affairs would be when a higher price succeeded in covering the higher marginal cost associated with additional production.

Such competition, a competition largely resembling that of animals for a fixed stock of prey, is what the pure-and-perfect-competition doctrine regards as ideal. However ironic it may be, the pure-and-perfect-competition doctrine seeks to establish as the competitive ideal precisely conditions resembling the law of the jungle.

When it denounces capitalism for a lack of competition, what it is denouncing is the fact that under capitalism, competition is the diametric opposite of the law of the jungle: it is a competition of producers in the production of wealth, not of consumers in the consumption of wealth.

The doctrine of “pure and perfect competition” marks the almost total severance of economic thought from reality. It is the dead end of the attempt to defend capitalism on a collectivist base.

Ironically, that attempt took hold in economics in the late nineteenth century (and has been gaining influence ever since) through the efforts of Victorian economists to refute the theories of Karl Marx on the subject of value and price. The rationing theory of prices was advanced as the alternative to the Marxist labor theory of value. The irony is that the “pure-and-perfect-competition” doctrine is *to the left of Marxism*.

Marxism denounced capitalism merely for the existence of profits. The “pure-and-perfect-competition” doctrine denounces capitalism because, as shown, businessmen refuse to suffer unnecessary *losses*. The argument of the supporters of “pure and perfect competition” is not that businessmen make excessive *profits* through any kind of “monopoly,” but that they are “monopolistic” in refusing to sell their products at a *loss*—which they would have to do if they treated their plant and equipment as costless natural resources that acquired value only when they happened to be “scarce.”

The fact that the pure-and-perfect-competition doctrine is, indeed, essentially an attack against business for refusing to accept unnecessary losses is borne out by the well-known study of Prof. Arnold Harberger.⁹⁴ In an attempt to measure the so-called deadweight welfare loss from “monopoly” in manufacturing in the United States, Harberger found that it turned out to be extremely small. Samuelson and Nordhaus write:

Harberger’s finding shocked the economics community. He found the welfare loss from monopoly was slightly less than 0.1 percent of GNP. In today’s economy, it would total about \$5 billion. One economist quipped that, if we believe this study, economists would make a larger social contribution fighting fires and eradicating termites than attempting to curb monopolies.

Many studies have refined and criticized Harberger’s original findings. . . . After reviewing all these subsequent analyses, a careful recent survey concludes:

“It appears that the deadweight welfare loss attributable to monopolistic resource misallocation in the United States lies somewhere between 0.5 and 2 percent of gross national product, with the estimates nearer the lower bound inspiring more confidence than those on the high side.”⁹⁵

Thus, despite all expectations, it now appears to be an established fact that the problem of monopoly is a rela-

tively small one by any standard. This, of course, does not stop Samuelson and Nordhaus, or the writers of all the other textbooks dealing with “microeconomics,” “industrial organization,” and “antitrust policy” from continuing just as before in making “monopoly” versus “pure and perfect competition” the sum and substance of their theoretical analysis. They report findings such as Harberger’s and then proceed to ignore them.

But there is a simple reconciliation between the “empirical” findings concerning the insignificance of the “monopoly” problem and the overwhelming preoccupation with it on the part of contemporary economic theory. This is the fact that a critical assumption of the so-called empirical studies appears to be that *marginal cost can be assumed to be equal to total average cost plus an allowance for earning the competitive rate of profit*. At any rate, this is how Samuelson and Nordhaus’s graphical depiction of the measurement problem shows matters.⁹⁶

Now if one takes marginal cost as this high, and thus uses as the measure of monopoly merely what amounts to *profits earned at above-average rates*, then indeed, the measure of monopoly will be small. (And even then, it will be far overstated, for it will include for the most part above-average rates of profit made by virtue of reducing costs of production, improving the quality of products, and successfully anticipating changes in consumer demand. Only a modest portion of above-average profits results from actual monopoly privilege.) The reason that, despite the insignificance of monopoly profits when computed in this way, they loom so large in contemporary economic theory is precisely the fact that, whether it is aware of it or not, contemporary economic theory is actually concerned with “monopoly” as the means of avoiding losses. This is what it sees everywhere and denounces everywhere, while the “empirical” studies, such as Harberger’s, automatically preclude such measurement by virtue of their assumption that marginal cost is equal to total average cost plus an allowance for earning the going rate of profit.

The Alleged Lack of “Price Competition”

The “pure-and-perfect-competition” doctrine distorts the facts of reality to a greater extent than did the traditional critiques of capitalism. Those critiques recognized that competition is a fundamental element of capitalism, but they denounced it. Capitalism, they claimed, is ruled by the “law of the jungle,” by the principles of “dog eat dog” and “the survival of the fittest.” The “pure-and-perfect-competition” doctrine proceeds from the same base as these earlier critiques, and is in full agreement with them in their objections to such characteristics of the process of competition as the continuous improvement in products, the variety of products, advertising, and the

existence of idle capacity. Both schools regard all these characteristics of competition as a “waste” of “society’s scarce resources.”

But the “pure-and-perfect-competition” doctrine regards these characteristics as “imperfections” and attacks capitalism on the grounds that capitalism *lacks* competition. Every industry, it asserts, is “imperfectly competitive” (with the barely possible exception of wheat farming). Every industry is guilty of “monopolistic competition” or “oligopoly.”⁹⁷

The competition that capitalism is accused of lacking—as a result of “monopolistic competition” and “oligopoly”—is called *price competition*. The nature of price competition, as contemporary economists see it, is indicated in the following quotation: “Analytically, the crucial thing about an oligopoly is the small number of sellers, which makes it imperative for each to weigh carefully the reactions of the others to his own price, production, and sales policies. The result is a strong pressure to collude to avoid price competition or to avoid it without formal collusion.”⁹⁸

Capitalism is accused of lacking price competition on the following grounds: if there are few sellers in a market, any seller who cuts his price must take into account the fact that the other sellers will match his cut—so he may be better off if he refrains from price cutting; thus prices will not be driven down to the level of “marginal cost” or to the point where they “ration” the benefit of “scarce” capacity.

Consider the denial of facts entailed in the accusation that capitalism lacks price competition. Every decade, since the beginning of the Industrial Revolution, commodities have become not only better, but also cheaper—if not always in terms of paper money (the value of which has been repeatedly reduced by the inflationist policies of governments), then in terms of the labor and effort that must be expended to earn them. What is it that has made producers lower their prices for the last two hundred years? Obviously, it is *price competition*.

Price competition exists even in the midst of inflation. Even under inflation, every firm is still interested in improving the productivity of the labor it employs. To the extent a firm succeeds in doing so, it is able to hold its price increases below the wage increases it must pay. Other firms in the same line of business which have not succeeded in raising the productivity of the labor they employ, or not to the same extent, must nevertheless keep their price increases in line with these price increases. The result is that if these firms wish to remain as profitable as before, ultimately, indeed, even to remain profitable and in business at all, they must further increase the productivity of the labor they employ. They simply cannot afford to fall too far behind. *This*, of course, is *price*

competition. It is a phenomenon known to virtually every businessman, but it is essentially unknown to contemporary economists, because of their arbitrary definition of price competition as the process of equalizing price with marginal cost. Their arbitrary definition simply blinds them to the existence of actual price competition. All that they look for in the world is what complies with their absurd definition; they have eyes for nothing else.

Actual price competition is an omnipresent phenomenon in a capitalist economy. But it is completely unlike the kind of pricing envisioned by the doctrine of “pure and perfect competition.” It is not the product of a mass of short-sighted, individually insignificant little chiselers each of whom acts to cut his price in the hope that his action will not be noticed by any of the others. The real-life competitor does not live in a rat’s world, hoping to scurry away undetected with a morsel of the cheese of thousands of other rats, only to find that they too have been guided by the same stupidity, with the result that all have less cheese.

The competitor who cuts his price is fully aware of the impact on other competitors and that they will try to match his price. He acts in the knowledge that some of them will not be able to afford the cut, while he is, and that he will eventually pick up their business, as well as a major portion of any additional business that may come to the industry as a whole as the result of charging a lower price. He is able to afford the cut when and if his productive efficiency is greater than theirs, which lowers his costs to a level they cannot match.

The ability to lower the costs of production is the base of price competition. It enables an efficient producer who lowers his prices, to gain most of the new customers in his field; his lower costs become the source of additional profits, the reinvestment of which enables him to expand his capacity. Furthermore, his cost-cutting ability permits him to forestall the potential competition of outsiders who might be tempted to enter his field, drawn by the hope of making profits at high prices, but who cannot match his cost efficiency and, consequently, his lower prices. Cost efficiency is the foundation of the ability to take business away from others in the field, insofar as one’s own cost reductions exceed theirs. Thus price competition, under capitalism, is the result of a contest of efficiency, competence, ability.

Price competition is not the self-sacrificial chiseling of prices to “marginal cost” or their day-by-day, minute-by-minute adjustment to the requirements of “rationing scarce capacity.” It is the setting of prices—perhaps only once a year—by the most efficient, lowest-cost producers, motivated by their own self-interest. The extent of the price competition varies in direct proportion to the size and the economic potency of these producers. It was

firms like Ford, General Motors, and A & P, and, more recently, the major Japanese producers—not a microscopic-sized wheat farmer or sharecropper—that have been responsible for price competition. The price competition of the rapidly growing Ford Motor Company early in this century reduced the price of automobiles from a level at which they could be only rich men's toys to a level at which even a low-paid laborer could afford to own a car. Later on, the price competition of General Motors was so intense that firms like Kaiser and Studebaker could not meet it. The price competition of A & P was so successful that the supporters of "pure and perfect competition" have never stopped complaining about all the two-by-four grocery stores that had to go out of business. And in recent years, the price competition of firms such as Toyota, Nissan, Sony, Mitsubishi, and Nippon Steel has set a pace that even the very best of American producers have found difficult to follow.

Price competition, it must be observed, frequently forces some of the sellers in an industry to sell at a price that is equal to or not far above *their* marginal costs, yet, at the same time, is substantially above the marginal costs of the more efficient, more competitively capable firms. This is part of the process by which the more efficient firms gain the business of the less efficient firms, which will be unable to replace their assets and thus unable to continue in business on the present scale. Indeed, the more efficient firms typically sell at prices *below* the marginal costs of a substantial portion of the capacity of the less efficient firms. Such prices are what keeps that less efficient capacity from serving the market, and thus competitively reserves the market to the more efficient firms.

Considerations of this kind explain why, when an industry is confronted with a substantial drop in the demand for its product, the result is a fall in price even though the demand for the industry's product is relatively inelastic and the industry is made up of few firms. What accounts for a price reduction that is consistent with rational self-interest in such circumstances is an inequality in the marginal costs of the different firms in connection with the capacity they had employed prior to the drop in demand. If the drop in demand idles capacity with a relatively low marginal cost of operation, while other firms continue to supply the market with capacity that has a relatively high marginal cost of operation, then it becomes to the self-interest of the firm with the lower-cost capacity to cut the price in order to make way in the market for its capacity. Cutting the price below other firms' higher marginal costs is the means of eliminating the higher-cost capacity of those firms from the market. This is genuine competition in adverse circumstances.

Such competition takes place throughout the eco-

nomic system in every recession. Yet contemporary economic theory is virtually incapable of comprehending how it can exist—that is, how prices can fall in the face of a drop in demand, or, indeed, under any other circumstances—apart from the conditions of "pure and perfect competition." What blinds its vision here is its inheritance from Alfred Marshall of the notion of "the representative firm."⁹⁹ It typically regards "an industry" as consisting of a mere multiplication of so many interchangeable, identical "representative firms." It thus proceeds on the assumption that all the firms in an industry have exactly equal efficiency and equal costs. In such conditions, there is obviously no basis for competition: no one can have any rational basis for expecting to succeed by competing. The moment anyone cuts his price, the other producers, who are assumed to be equally efficient, cut theirs in response. The result is that the only possible gain for a producer in cutting his price is the gain that would exist if there were only one producer. On this basis, contemporary economics concludes that what it calls "oligopoly" is essentially the same in its effects as "monopoly." For it appears to it that it will pay an "oligopolist" to cut his price only when it would pay a "monopolist."¹⁰⁰

Competition, centering precisely on an *inequality* in the productive efficiency of firms, is the means by which continuous progress and improvement are brought about, in terms both of falling real prices of products and ever better products. Indeed, nothing could be more pure and perfect—in the rational sense of these terms—than the competition that takes place under capitalism. As the result of this competition, generation after generation, in industry after industry, one massive improvement in production succeeds another, and the best of the products of the past cease to be good enough for the present. At the same time, everything becomes more and more affordable to more and more people. This is what the whole of Part C of the preceding chapter and, indeed, the whole of this book has shown.

The ideal of the "pure-and-perfect-competition" doctrine, however, is a totally stagnant economy—the "static state," as it is called—in which production and consumption consist of an endless repetition of the same motions.¹⁰¹

It is in the name of this "ideal" that the supporters of "pure and perfect competition" attack the constant introduction of new or improved products, the ever-growing variety of products, and the advertising required to keep people abreast of what is being offered.

And only from the standpoint of this "ideal" can one declare that idle capacity is a "waste"—for only in a "static state" would there be no need for any unused capacity.

The supporters of “pure and perfect competition” are aware of the fact that their doctrine is inapplicable to reality. This does not trouble them. Their view is expressed by Professor Wilcox, who casually observes: “Perfect competition, thus defined, probably does not exist, never has existed, and never can exist. . . . Actual competition always departs, to a greater or lesser degree, from the ideal of perfection. Perfect competition is thus a mere concept, a standard by which to measure the varying degrees of imperfection that characterize the actual markets in which goods are bought and sold.”¹⁰²

This “concept” divorced from reality, this Platonic “ideal of perfection” drawn from nonexistence to serve as the “standard” for judging existence, is one of the principal reasons why businessmen have been imprisoned, major corporations broken up and others prevented from expanding, and why economic progress has been retarded and the improvement of man’s material well-being significantly undercut. This “concept” is at the base of antitrust prosecutions, which have forced businessmen to operate under conditions approaching a reign of terror.

The doctrine of pure and perfect competition is a leading manifestation of the influence of irrationalism and mysticism in contemporary economics. It can be taken as an illustration of the proposition that while unreality and nonexistence as such can have no consequences, those who are confused enough to advocate them, do. It belongs hopefully to the last, and certainly to the most convoluted and absurd phase of the denunciations of capitalism as a system of monopoly.

11. A Further Word on Cost of Production and Prices

The discussions of the marginal revenue and pure-and-perfect-competition doctrines make clear that the reaction to classical economics’ exaggeration of the explanatory role of cost of production as a determinant of prices has gone too far, in two respects.

First, cost of production operates to set many prices far below what they would be if they were determined on the basis of the direct marginal utility of the good concerned. This, of course, is the case with respect to some necessities and virtually all components and spare parts used in manufactured goods.

Second, cost of production operates to establish prices at a point that is above what they would be if producers did in fact have to regard their plant and equipment and intellectual property as not deserving to command an allowance in the price of the product because their renditions of service were not scarce. The fact that producers do not have to regard their plant and equipment in this way is, of course, what makes it possible for prices to be below the direct marginal utility of the specific goods concerned, because producers then have the productive capacity on hand immediately to make more of the goods available. And the fact that they do not have to regard their intellectual property in this way is what underlies their incentive and ability to go on introducing further productive innovations, which steadily reduce prices in real terms.

Thus, prices are very often lower than one would expect on the basis of the direct marginal utility of the product. At the same time, they are typically higher than corresponds to the marginal utility of the full available supply of the means of producing the product—viz., the full available supply of renditions of service that the plant and equipment and, even more, the knowledge of the requisite methods of production, is capable of providing. In both cases, prices are pulled toward cost of production—the full cost of production.

In the first case, they are pulled in a downward direction; in the second case, in an upward direction. In the first case, cost of production communicates the marginal utility of the means of production in other employments and pulls the marginal utility and price of products in specific industries down to conform with that wider marginal utility. In the second case, cost of production on the part of potential outside entrants, together with an allowance for the going rate of profit, sets the upper limit to which producers can raise the price of their product without encouraging outside competition—except insofar as their products possess premium quality. It thus limits the extent to which prices can exceed a correspondence to the marginal utility of the full available supply of means of production. As stated, and it cannot be too strongly stressed, such excess of price is an essential foundation for the cheapness of price in comparison with the direct marginal utility of many goods and for the progressive decline in prices in real terms.

6. Strictly speaking, in order for the freedom of competition to reduce hospital rates to a level corresponding to the necessary costs of providing hospital care, together with a competitive rate of profit, and then to reduce those necessary costs, more would be required than freedom from licensing. Freedom from other forms of government regulation that artificially increase costs would also be necessary. This is because today’s outlandish hospital rates do not rest on a foundation of exorbitant profits, but on a foundation of artificially created costs caused by government intervention in medical care. The freedom of competition that escape from licensing is to make possible must be understood as allowing the competitors to avoid all such artificial costs. Such costs include the practice of so-called defensive medicine in order to avoid irrational malpractice suits.

31. As later discussion of saving and capital formation will make clear, the extent to which successful mergers, or anything else which serves to increase real wealth and capital, are accompanied by an increase in the monetary value of invested capital in the economic system as a whole, depends on the rate of increase in the quantity of money. What is essential here is only that successful mergers result in the formation of more new capital in real terms, and thus in the basis for the formation of new and additional firms.
32. It must be noted that this conclusion is not contradicted by statistics alleging a growing concentration of the capital of the American economic system in the hands of the 200 or 500 largest corporations. At the same time that this phenomenon has been going on, foreign trade has become of greater importance and the capital of America’s major trading partners has increased much more rapidly than that of the United States. Thus, the ratio of the capital controlled by the 200 or 500 largest American corporations to the total capital employed in serving the American market has sharply fallen over the last generation!
33. For a defense of insider trading, see below, pp. 395–396.
34. See above, p. 127.
35. For an example of this error, see Samuelson and Nordhaus, *Economics*, pp. 571–572.
36. *Ohio v. Standard Oil Co.*, 49 Ohio, 137 (1892).
37. Cf. John S. McGee, “Predatory Pricing: The Standard Oil (New Jersey) Case,” *The Journal of Law and Economics*, October, 1958, p. 144.
38. The situation here is similar to the case of partial price controls raising prices on the uncontrolled portion of the supply. See above, pp. 250–252 and 254–256.
39. Cf. Wayne Leeman, “The Limitations of Local Price Cutting as a Barrier to Entry,” *Journal of Political Economy*, August, 1956, pp. 331–332.
40. Cf. *ibid.*, p. 330.
41. In fact, Rockefeller did buy out small competitors at premium prices, but not in order later on to charge higher prices—rather, in order to achieve the economies of larger-scale operations. In this way, the small competitors shared the gains of merging and achieving economies of scale. See John S. McGee, “Predatory Pricing.” See also Leeman, “Limitations of Local Price Cutting,” p. 332.

42. Leeman, "Limitations of Local Price Cutting," pp. 332–333.
43. Cf. John S. McGee, "Predatory Pricing," especially p. 168.
44. This is the same mentality of state worship as is present when people credit government-sponsored research efforts with bringing about major advances in the production of civilian goods, in the process ignoring the essential context of the existence of a capitalist economic system with its profit motive and freedoms of individual initiative and competition, without which no civilian use would ever be made of any such research. (On this subject, see above, p. 277, especially n. 16.) It is the same mentality that is present above all in that combination of unsurpassed ignorance and arrogance that blithely ignores the economic planning that takes place every day under capitalism on the part of millions and tens of millions of private business firms and individuals, and regards economic planning as a capacity unique to the state, which is utterly incapable of planning an economic system and characteristically bungles whatever lesser planning it may undertake. (Concerning this subject, see above, pp. 137–139 and 269–273.)
45. For further analysis pertaining to the post–World War II success of the Japanese economy in comparison with the American economy, see below, pp. 622–629, where the United States can be thought of as the stationary economy depicted in Figure 14–4 on p. 624, and Japan as the progressive economy depicted in Figure 14–5 on p. 625. That analysis explains the role both of relative rates of saving and relative degrees of economic freedom in bringing about capital accumulation and economic progress. See also pp. 831–834.
46. Dudley Dillard, *Economic Development of the North Atlantic Community* (Englewood Cliffs, N. J.: Prentice-Hall, 1967), pp. 409–410.
47. An investigation of the actual facts concerning Standard Oil's dealings with the railroads, undertaken by someone who understands the principles of sound economics, would make an excellent subject for a doctoral dissertation and subsequent book.
48. In reality, it is likely that the elasticity accompanying ten 10 percent increases in supply would not be uniformly one-tenth of the elasticity of a doubling of supply, but would show some variation, with some of the 10 percent increases in the industry's supply being accompanied by lesser or greater price reductions, which, nevertheless, would cumulatively add up to a 40 percent reduction in price accompanying a doubling of supply.
49. Interestingly, Samuelson and Nordhaus show some modest awareness of the fact that potential increases in competitors' output can increase the elasticity of demand facing a given firm. See Samuelson and Nordhaus, 13th ed., pp. 609–610. They seem utterly unaware, however, of the critical role played by outsiders' costs.
50. See below, pp. 417–420.
51. Application of the principle to the oil industry was present in the discussion, back in Chapter 7, of the injustice of blaming the oil industry for the oil shortage or for any increase in the scarcity of oil. See above, p. 236.

54. *Ibid.*, 2:244–245.
55. Böhm-Bawerk uses the term "marginal product" here to refer to a distinct product of a different type, not, as is the practice in contemporary economics, to the gain or loss of a product of a given type attributable to the presence or absence of a unit of a factor of production.
56. It must be pointed out that the existence of inventories, which can be drawn down in response to an increase in demand, before additional production succeeds in increasing supplies, and which can be temporarily built up in response to a decrease in demand, before production is cut back, makes it unnecessary that production be adjusted instantaneously to changes in demand. The extent to which demand is postponable also introduces a measure of flexibility in how quickly production must be adjusted to changes in demand in order to maintain a connection between prices and costs.
57. Böhm-Bawerk, *Capital and Interest*, 2:173–176. (The permission granted by Libertarian Press to quote this very long passage is gratefully acknowledged.) See also *Capital and Interest*, 3:Excursus 8, and Böhm-Bawerk's untranslated article "Wert, Kosten, und Grenznutzen," *Jarhbuch für Nationalökonomie und Statistik*, Dritte Folge, 3:328.

62. It will be found that the substance of what is said here concerning patents and copyrights applies equally to trade secrets. The only difference is that in the case of trade secrets there is no fixed time limit within which competitive advantages must fall into the public domain. That time may come sooner or later than is the case under patents and copyrights.
63. See above, pp. 388–389.
64. On the subject of collectivized medical costs, see above, pp. 148–150.
65. These and any other possible exceptions all pertain to the use of physical force, which is the essential feature of government power. This is the one activity which, insofar as it cannot be entirely eliminated, must be tightly controlled and regulated, so that the only force used is the appropriate minimum necessary for defense and retaliation against the initiation of force. In a fully free society, government would be the only controlled and regulated institution.
66. Insurers and mortgage lenders would undoubtedly also require adherence to various safety precautions in the construction and maintenance of the properties they insured or lent money on.
67. See above, pp. 408–414.

CHAPTER 11

THE DIVISION OF LABOR AND THE CONCEPT OF PRODUCTIVE ACTIVITY

PART A

THE ROLE OF MONEYMAKING IN PRODUCTIVE ACTIVITY

1. The Division of Labor and Productive Activity

The existence of the division of labor exerts an influence on the nature of productive activity that is no less profound than its influence on the institutions of private ownership of the means of production, economic inequality, and economic competition. An understanding of this influence is sorely lacking in the present-day world, however. Unfortunately, most people hold a concept of productive activity that would be appropriate only in a non-division-of-labor society.

The Doctrine That Only Manual Labor Is Productive

The notion of productive activity that the majority of our contemporaries hold is that productive activity is *manual labor*. Productive activity and manual labor are seen as virtually interchangeable concepts. For evidence of this proposition, consider the distinction drawn in the United States by the Internal Revenue Service between “earned income” and “unearned income.” “Earned income” is held to be wages and salaries. Profits, interest, and dividends, on the other hand, are held to be “unearned income.” The basis of the distinction is that the

first two are perceived as being received by virtue of the performance of labor. The last three are perceived as being received without the performance of labor.

Exactly the same ideas are held by the labor unions, who believe that their members, who are almost all manual workers, are the people truly responsible for production and thus the rightful recipients of all income. It is on this basis that the unions feel entitled to appropriate every last dollar of profits that they possibly can for wage increases. In their view, the profits rightfully belong to their members in the first place.

The view that productive activity and manual labor are one and the same is an essential doctrine of Marxism and is held by every socialist government. It is in the name of this proposition that the Marxists have sought to expropriate private property and establish socialism, so that the “unearned income” can be given back to its alleged rightful owners, the manual workers. Marxism also provides intellectual inspiration for the labor unions and the tax authorities. It is the leading source of their conviction that they are appropriating unearned income for the benefit of those who are entitled to it.

But the notion that only manual labor is productive long predates Marxism. It was propounded by the classical economists in most respects, and, more than that, it is a reasonable conclusion if one’s only experience is that of the conditions of a non-division-of-labor society. In a non-division-of-labor society, where production means, essentially, the growing of food, the making of clothing,

and the building of shelter, on a household basis, the producers are those who do these things, and the nonproducers are those who do not. In a non-division-of-labor society there is no room for any category of producer much beyond that of toiler in the field or at the loom.

The doctrine that only manual labor is productive—a mental inheritance originating in the primitive conditions of earlier times and then frozen, as it were, by virtue of a failure to consider the radically new conditions established by the development of the division of labor—underlies the condemnation of an immense proportion of the productive activity of a capitalist society. Because of its influence, many people have no conception of perhaps what half of the present-day economic system is for. In addition to its most serious consequence of excluding the activities of businessmen and capitalists from the category of productive activity, the manual-labor doctrine excludes many other important productive activities performed in a capitalist society. Thus, retailing and wholesaling are widely perceived as having nothing to do with production, but serving merely as a pretext for adding on “markups” to the prices charged by manufacturers and farmers. Advertising is routinely considered to be non-productive, indeed, to be inherently fraudulent. The stock and commodity exchanges are regularly denounced as mere “gambling casinos,” with virtually no connection to productive activity. The banking and financial system in general is regarded with similar suspicion.

The manual-labor doctrine rests on an ignorance of the requirements of a division-of-labor society and is far too narrow in its view of what constitutes productive activity. A proper concept of productive activity must make room for the activities of businessmen and capitalists, retailers and wholesalers, and advertisers, and of the stock, bond, and commodity exchanges and financial system in general.¹

In another respect, however, the manual-labor doctrine leads to a view of productive activity that is actually far too broad. For it regards as productive activity *all* activity that represents manual labor. Thus, it leads to the very popular notion that there is no basis for distinguishing between the labor of unpaid housewives and that of paid housekeepers who perform the same work. Both are held to be equally productive on the grounds that both perform the same manual labor. It also leads to the very popular view (contrary to the teachings of Adam Smith on this subject) that there is no basis for regarding the labor of government employees as inherently unproductive, inasmuch and insofar as they perform the same type of physical work as the employees of private business.

The appropriate concept of productive activity for a

division-of-labor society has a variety of characteristics which distinguish it from the concept of productive activity appropriate to a non-division-of-labor society. The aspect which can most easily be explained in a way that is fully self-contained is the connection between productive activity and *moneymaking*. As a result, this aspect will be our starting point in the elaboration of a proper concept of productive activity. It will take us into the distinction between production and consumption in the context of a division-of-labor society, between capital goods and consumers' goods, producers' labor and consumers' labor, and producers' loans and consumers' loans. It will make us aware of the existence of a category of spending—*productive expenditure*—that our investigations in later chapters of this book will show to be larger than consumption expenditure and to be the source of most consumption expenditure, and yet whose very existence is almost entirely overlooked in contemporary economics.²

The application of the concept of productive expenditure to economic analysis will take place to an important extent later in this chapter, in the critique of the conceptual framework of the Marxian exploitation theory and the validation of the productive activity of businessmen and capitalists. Productive expenditure and the closely related concepts of capital goods and producers' labor will also turn out to be the foundation of the system of aggregate economic accounting that I develop in Chapter 15, and an essential basis of the theory of aggregate profit and the average rate of profit that I present in Chapter 16.

2. Productive Activity and Moneymaking

In a division-of-labor economy, the earning of money becomes an essential aspect of productive activity. This is because in order to live in such an economy, one must obtain the goods and services of other people. Those goods and services are not given away for free, nor, to any significant extent are they, or could they be, obtained through barter. To obtain the goods and services of others, one must possess *money*. Thus, if one's productive activity is to be appropriate to life in a division-of-labor society, that is, to be the means of obtaining the goods and services of others, it is essential that it be moneymaking. Only then, does one's activity make it possible for one to share in the benefits of a division-of-labor society. However productive an activity may be in a purely physical sense—that is, result in physical products—it is not productive in the context of a division-of-labor economy unless it is carried on for the purpose of earning money. If it is not carried on for the purpose of earning money, it does not provide the means of obtaining the goods and services of others, and it thus renders one's

activity incapable of providing for the support of one's life in the context of a division-of-labor society. Without the earning of money, one must attempt to produce and live at a level somewhere between that of Robinson Crusoe and the inhabitants of Tobacco Road.

Thus, in the context of a division-of-labor society, productive activity can appropriately be defined, just as it often is in practical life, as *activity the purpose of which is the earning of money*.

I refer to purpose rather than to the actual fact of whether or not money is earned, because purpose is more fundamental. An activity is productive or economic so long as moneymaking is its purpose, even if, in a given instance, it fails to make money, or actually loses money. The principle is the same as applies to a carpenter, say, who is nonetheless a carpenter, even though, on occasion, the actual result of his action may not be the result he intended and may even be destructive of some of his material; or to a musician, who, on occasion, strikes a sour note. By the same token, the accidental receipt of money resulting from the performance of an activity would not be sufficient to render it productive—any more than, say, the accidental typing of a word by a monkey playing with a typewriter would qualify as writing. The *purpose* of moneymaking is the essential element.

To avoid a possible misunderstanding, it must be pointed out that common criminal activities, such as robbing banks, do not qualify as productive activity, even though the ostensible purpose of such activities may be the bringing in of money. The *earning* of money, as opposed to its mere receipt, implies the existence of voluntary trade, which precludes the obtaining of money by force or fraud.

In addition, activities which can be proven to be inherently destructive of innocent human life, such as, presumably, the manufacture and sale of narcotics, are not to be classified as productive, even if the money is obtained from the customer without the use of force or fraud. This is because the concept of productive activity ultimately rests on the promotion of human life and well-being and must always be consistent with that ultimate purpose.³

It must also be noted that the standard of human life and well-being implies that the paid manufacture of weapons of defense can come under the heading of productive activity. For example, American defense contractors, who produce weapons to defend a division-of-labor, capitalist society against foreign aggression, perform an invaluable service on behalf of the protection of innocent human life. The fact that they are paid for their goods and services qualifies their activity as fully pro-

ductive in the sense appropriate to life in a division-of-labor society.

The main concern of this discussion, of course, is not the moral aspects of productive activity, but the economic aspects. And returning now to the economic aspects, it should be clear that manual labor is, indeed, too broad a standard for gauging productive activity. Manual labor is not productive if it is not performed for the purpose of earning money. In such a case, it does not enable the worker to obtain the goods and services he requires from others. Thus, his labor is not productive in the sense required by life in a division-of-labor society.

The recognition of this fact implies that the labor of housewives, for example, is not productive, while the physically identical labor of paid housekeepers is productive. Even though the physical labor of the two is the same, there is an essential difference between the two cases, in that because the labor of the housekeeper is paid, it is a source of her being able to obtain the goods and services of others, while because the labor of the housewife is unpaid, it is not a source of her being able to obtain the goods and services of others.

Consumptive Production

In a division-of-labor society an activity that is physically productive but is not carried on for the purpose of earning money is not only not to be classified as productive, but actually represents *consumption*.

In a division-of-labor society, the physically productive activity of every individual begins with the use of means of production—materials, tools, equipment, and so forth—produced by others, and for which money has had to be expended. These means of production are physically used up or worn out in the course of production. Sooner or later, they must be replaced, which will require fresh outlays of money. If their use does not bring in money, they cannot be replaced, except by means of an outside source of funds. They certainly cannot be replaced by virtue of the nonmoneymaking activity in question. Thus, the activity in question is a *consumptive production*, in that it uses up the means of production with which it begins and does not make possible their replacement.

The activities of housewives and home hobbyists provide countless instances of consumptive production. For example, it is certainly an act of physical production when a housewife makes her own clothes, or when a hobbyist makes his own furniture. It is an act of physical production when a housewife bakes a cake or prepares a meal, and even when one simply makes a sandwich or butters a piece of bread. But all of this production is a consumptive production in that the production requires

the using up of materials and the wearing out of tools, equipment, or implements, all of which must sooner or later be replaced, while the product disappears without bringing in the money necessary for their replacement.

3. Productive Expenditure and Consumption Expenditure

The above discussion of consumptive production implies that it is necessary to distinguish between two fundamentally different types of expenditure: *productive expenditure* and *unproductive expenditure*—which latter represents *consumption expenditure*.

Productive expenditure is *buying for the purpose of subsequently selling* (and, implicitly, at a profit, for there can be no other reason to buy for this purpose).

Unproductive expenditure is buying *not* for the purpose of subsequently selling. It is buying for any other purpose than subsequently selling.

Productive expenditure is synonymous with *reproductive expenditure*, for it is money which is both laid out and brought back by virtue of productive expenditure.

Though all expenditure represents a using up of funds at hand, the term “consumption expenditure” can be employed as a synonym for unproductive expenditure, and the term “consumer” can be reserved exclusively for those who make unproductive expenditures—insofar as they make them. This is because, in the context of the whole process of which it is a part, productive expenditure does not constitute a using up of money, while unproductive expenditure does constitute a using up of money. Funds that are productively expended subsequently return, usually with the addition of a profit. Funds that are unproductively expended, as a rule, either do not return at all or return only in a smaller amount, and thus are simply consumed. Funds that are productively expended are advanced against the receipt of a larger sum of money, while funds that are unproductively expended simply disappear from their owner’s possession. In the one case, there is replacement and increase. In the other, simply decrease.

For example, both a restaurant and a housewife buy roast beefs. The restaurant cooks the roast beef, serves it, and is paid for it by its customers, who physically consume it. In this way, its expenditure is returned to it and, most likely, with the addition of a profit. In the context of the entirety of the process, the restaurant has not consumed its funds, but has obtained additional funds, which are available for other purposes, such as expanding its business or enabling its owner to make consumption expenditures. The restaurant’s expenditure is both self-sustaining, in that it subsequently makes possible the purchase of a second, replacement roast beef, and more

than self-sustaining, in that it subsequently makes possible the purchase of additional goods besides.

The housewife, on the other hand, cooks the roast beef, serves it, and, of course, is not paid for it. The roast beef simply disappears in the physical consumption of her family, and with it, all trace of the housewife’s expenditure. Her money is simply used up and gone forever. Her purchase of a roast beef does not provide any funds for the subsequent purchase of a second roast beef, but simply annihilates, as it were, the funds expended. Her purchase, once made, is not thereafter self-sustaining, but on each new occasion must be sustained by the infusion of fresh funds from outside sources. If a second roast beef is to be purchased to replace the first, and then a third to replace the second, and so on, the funds must be obtained from an outside source, such as, typically, a job held by the housewife’s husband.⁴

Similarly, both a housewife and a laundromat buy washing machines. In the course of their use, both machines undergo wear and tear and natural deterioration. Eventually, they will have to be scrapped, at which time they will command prices much below their initial purchase price. Every time the laundromat’s machine is used, however, it is paid for this use. And out of the payments thus received, it obtains the money to pay for repairs of the machine and, when the day arrives, for a new machine. Plus, it normally earns a profit on the machine, and the laundromat’s owner, therefore, like the restaurant’s owner, can purchase more than just a replacement.

The housewife does not receive any payment for the use of her machine. Both repair bills and the difference between the price of a new machine and the eventual scrap value of her present machine have to be met from outside sources of revenue. Her washing machine is used up more slowly but just as certainly as her roast beef, and with it, again, disappears, if not the whole, at least the major part of her expenditure for it.

From a physical standpoint, to be sure, the washing machine is productively consumed, in making clothes clean. It differs in this respect from the roast beef dinner, which is unproductively physically consumed (though not from the raw roast beef, which is productively consumed in being cooked.)⁵ But it makes no difference. This is because the products of the washing machine, the cleaned clothes, are unproductively physically consumed without bringing in any money—as they would for a laundry or laundromat. At most, recognition of the fact that the housewife’s washing machine has a physical product might cause us to say that the housewife’s expenditure for the machine, instead of disappearing bit by bit with each operation of the machine, disappears bit by bit each time the clothes it cleans get dirty again.

It happens, of course, that productive expenditures are sometimes accompanied by losses, while consumption expenditures occasionally result in gains. But, as previously noted, these are accidental phenomena, not following from the nature of the activity, and do not necessitate any change in the classification of any given expenditure.

The great, practical difference between productive expenditure and consumption expenditure is that an individual grows richer through productive expenditure and poorer through consumption expenditure. Two people, both beginning with identically the same sum of money (we might imagine two brothers sharing equally in an inheritance), the one productively expending his funds, the other unproductively expending his funds, will almost necessarily arrive at opposite stations in life. The one will be richer; the other will be impoverished.

4. Capital Goods and Consumers' Goods

Closely paralleling the concepts of productive expenditure and consumption expenditure are the concepts of producers' goods and consumers' goods.

Producers' goods or, what is a synonymous expression, capital goods, are goods purchased *for the purpose of making subsequent sales*.

Consumers' goods are goods purchased *not* for the purpose of making subsequent sales.

The distinction between capital goods and consumers' goods is exclusively one of the purpose for which the goods are purchased—*for* business purposes or *not* for business purposes—and not at all a matter of their physical characteristics. The roast beef purchased by a restaurant and the washing machine purchased by a laundromat are both capital goods. Exactly the same kind of roast beef and washing machine purchased by a housewife are consumers' goods.

The reason that the purpose for which they are purchased is the crucial distinction has already been indicated. Physically, the roast beef and the washing machine are consumed, whether purchased for business purposes or purchased not for business purposes. In both cases, there is, in this instance, a physical production that takes place in which the goods are consumed: the raw roast beef is consumed in producing a cooked one, and the washing machine is consumed in producing cleaned clothes. And thus, both for the housewife and for the business enterprises, there is even a productive consumption in the physical sense.

But beyond the physically productive consumption comes a physically unproductive consumption: the cooked roast beef is eaten and the cleaned clothes get dirty in the wearing. At this point, all trace of the goods purchased by the housewife has simply disappeared from

her possession. (In the case of durable goods, such as the washing machine, all trace of the relevant *portion* of the good's life has disappeared.) But by this same point, or earlier, the restaurant and laundromat have obtained the means of replacing, and more than replacing, the goods they have purchased. The goods they have purchased, when one allows for their replacement by way of purchase, with funds earned from their very own employment, are *not* consumed—they are replaced by virtue of their own use, together with a surplus.

The roast beef of the restaurant and the washing machine of the laundromat, by virtue of being purchased for the purpose of making subsequent sales, and then by way of using the resulting sales proceeds to make replacement purchases, are *reproductively employed*. The restaurant's roast beef and the laundromat's washing machine are, as it were, employed in the production of roast beefs and washing machines, or their equivalent in other goods, as wheat seed is employed in the production of wheat. And thus in the fullest sense they represent wealth employed in the production of wealth, and are capital goods, even though from a strictly physical standpoint, a roast beef cannot be used to produce roast beefs, and a washing machine cannot be used to produce washing machines.

Actually, it is not necessary that the restaurant or laundromat use its proceeds to buy specifically a second roast beef or a second washing machine, or even a good playing the same role in production as a roast beef or a washing machine. What counts is that, because he earns revenue by the use of the roast beef or washing machine, the restaurant's or laundromat's owner is enabled to obtain the *equivalent*, and more than the equivalent, of his roast beef or washing machine by the time it is physically consumed, while a housewife is not in this position. Whether that equivalent takes the form of a new roast beef or washing machine, of goods employed in a different line of business, or even of consumers' goods, the essential fact remains that he is engaged in a process whose inherent tendency is to preserve and increase his initial wealth rather than decrease it.

Classification of Capital Goods and Consumers' Goods Not Based on Physical Characteristics

The principle that goods are capital goods or consumers' goods depending only on the purpose for which they are purchased, and not on their physical characteristics, needs to be illustrated with additional examples. Thus, a box of breakfast cereal purchased by a grocer or a restaurant is a capital good; one purchased by a housewife is a consumers' good. Knives and forks and tables and chairs purchased by a restaurant are capital goods; those purchased for (nonbusiness) use in the home are

consumers' goods. A house purchased in order to be rented out is a capital good; one purchased in order to be occupied by its owner is a consumers' good. A lathe purchased by a business enterprise is a capital good; one purchased not for moneymaking purposes, for instance, by a hobbyist, is a consumers' good. A bulldozer purchased by a construction company is a capital good; a bulldozer purchased by a government, say, for use in constructing military airfields or dams for flood-control projects, is a consumers' good—as, indeed, would be a bulldozer factory that was not operated for profit-making purposes. Freeways, public school buildings and their fixtures, nonprofit hospitals and their equipment, courthouses, military bases, fire houses and fire trucks, government river and harbor improvements—all these are consumers' goods, because they are not operated for the purpose of earning money, and thus do not make possible their own replacement when they have been physically consumed.

The acquisition of every good, except the crudest, most primitive kind, presupposes an outlay of money. Money must be spent not only if one wishes to acquire a good ready-made, but even if one wishes to produce the good oneself. All physical production worthy of the name can begin only after an outlay of money has been made to provide the means with which to produce. Without money to buy food, an oven, knives, forks, dishes, tables and chairs, and a structure within which to cook and serve, neither a housewife nor a restaurant could do more perhaps than serve wild berries on a stone, in a cave. Without money to buy steel, concrete, and the use of construction equipment, and to hire labor, neither a construction company nor a government could do more perhaps than build a dam that would compare unfavorably with those built by beavers.

While an expenditure of money is at the base of all physical production in a division-of-labor society, only the activity of *business enterprises* is so designed as to recoup this expenditure. It cannot be too strongly stressed that because of this only business activity is self-sustaining. The activity of all others, however massive and durable the goods they may employ, however complex and elaborate their physical production may be, is not designed to recoup this expenditure. The goods of these others, therefore, are all on the path toward disappearing from their possession without leaving a trace. They either reach a point of unproductive physical consumption within their possession—as, for example, the housewife's roast beef dinner and her clean wash; or they simply pass from their possession—as, for example, government gifts of surplus wheat. In either case, having made an unproductive expenditure, the party who made it has less and less to show for it until absolutely nothing

at all would remain, were it not for the infusion of fresh funds received from outside sources.

Government a Consumer

A government dam or road or factory, therefore, is consumed just as fully and in the same sense as a housewife's roast beef or washing machine; and for this reason, like these, they are consumers' goods, not capital goods. And in the same sense as the housewife, the government is not a producer, but a consumer, who is dependent on producers. All of its physical production, like hers, is, in the last analysis, a consumptive production. It is a production which cannot replace the means with which it began and which ultimately leaves no trace in the government's possession; it is a production which leaves the government poorer by the amount of funds it has expended. In order to continue the activity, resort must be had to an external source of funds—in the government's case, the taxpayers or the printing press.

Producers' Labor and Consumers' Labor

The distinction between capital goods and consumers' goods applies equally to labor. Labor employed for the purpose of (its employer) making subsequent sales is producers' labor. Labor employed *not* for the purpose of (its employer) making subsequent sales is consumers' labor.⁶

It must be stressed that the distinction between producers' labor and consumers' labor is always from the perspective of the employer, not the employee. From the perspective of the employee, all labor is productive which is performed for the purpose of earning money. Those whose work is consumers' labor earn money no less than those whose work is producers' labor, and they are productive in the sense appropriate to life in a division-of-labor society. The same is true, of course, of those who produce consumers' goods. They too earn money and are productive in producing consumers' goods. The distinction both between capital goods and consumers' goods, on the one side, and between producers' labor and consumers' labor, on the other, is from the perspective of the buyer—in the one case the customer for the good, in the other, the employer of the labor.

Thus, for example, a maid employed by a hotel is producers' labor. The same maid employed by a housewife is consumers' labor. In the one case, the payment of the maid's wages is a source of subsequent revenue to her employer, which enables the employer to continue the payment of her wages and to purchase other things besides. In the other case, the payment of the maid's wages is simply a use of the revenue of her employer, with the means for each fresh payment of wages having to be supplied by an outside source of funds. The owners

of a hotel grow richer by the employment of a maid—for her work helps to bring in paying guests—while a housewife grows poorer by the employment of a maid; that is the practical difference.

Further to illustrate the concepts: a secretary employed by a business enterprise is producers' labor; one employed by a government bureau or private nonprofit organization is consumers' labor, as is one employed by a wealthy individual to handle social engagements.⁷ A welder employed by a private shipyard is producers' labor; one employed by a naval shipyard is consumers' labor. A musician employed by a night club owner or concert promoter is producers' labor; one employed by a bride's father to play at her wedding is consumers' labor. All government employees, from judges to public school teachers, whether their services are necessary and beneficial or not, are consumers' labor. The payment of their wages uses up the government's revenue rather than providing the government with the means of earning revenue. The fact that the government must turn to taxes to maintain its operations is the result precisely of the fact that its expenditures do not generate the revenue to sustain them.

Producers' Loans and Consumers' Loans

The same fundamental distinction that applies to expenditures, goods, and labor applies also to loans. Loans taken out for the purpose of the borrower making subsequent sales are producers' loans. Loans taken out *not* for the purpose of the borrower making subsequent sales are consumers' loans.

Again, the great practical distinction is that producers' loans, by virtue of bringing in sales revenues, provide the funds required for their own repayment, and usually more besides. Consumers' loans, on the other hand, must be repaid by means of an outside source of revenue, because the expenditure of the funds which are borrowed does not serve to bring in funds.

Government Borrowing

It should be obvious that government borrowing is in the category of consumer borrowing. But there is a vital difference between the borrowing of private consumers and the borrowing of the government. Namely, when private consumers borrow, it is they as individuals who are responsible for repaying. When the government borrows, the responsibility for repayment is that of the taxpaying public, including, insofar as they too are taxpayers, the *lenders!* Indeed, if as is very often the case, the government chooses to repay by means of inflating the money supply, the lenders can easily end up paying for the greater part of the government's borrowing.

There are sound reasons for private individuals to

borrow as consumers—namely, to be able to have the enjoyment of goods sooner rather than later. By being able to borrow the price, or the better part of the price, of a house or automobile, an individual can obtain the enjoyment of the good years sooner than he could if he first had to save up the full price himself. But in the case of government borrowing, any such possible advantage is more than outweighed by the injustice of imposing an unchosen obligation on individual citizens to repay who may attach little or no value to the purpose for which the funds are spent. Indeed, government borrowing obligates individuals to repay who may be too young to have a voice, or not even have been born, at the time the decision to borrow is made. It is thus incompatible not only with the free choice of individuals but also with the theory of representative government, because it obligates people who cannot be represented when the decision to borrow is made—at least not by representatives of their own choosing.

Capital Goods and Consumers' Goods Internally Produced; Other Revenues

In defining capital goods and consumers' goods, it was necessary deliberately to define them in a way that, strictly speaking, is too narrow. This was required in order to exhibit their distinguishing characteristic in the strongest possible light, free of all considerations that might divert attention from the essential point.

Taken strictly, those definitions imply that every capital good and every consumers' good must itself be purchased. That, of course, is not necessary, and no such idea was intended to be conveyed. In fact, a number of the illustrations offered contradict such a view.

Many capital goods and consumers' goods are not themselves purchased, but are produced, with means of production that have been purchased. For example, in the illustration concerning the restaurant and housewife, the *cooked* roast beef as well as the raw roast beef was a capital good in the one case and a consumers' good in the other, even though only raw roast beef was purchased. By the same principle, not only the boxes of breakfast cereal purchased by a grocer or a restaurant are capital goods, but also those in the inventory of the manufacturer of breakfast cereals, who purchases only the means of producing them, not boxes of breakfast cereal themselves. Again, on the same principle, a privately owned steel mill is a capital good even though it itself may not be purchased, but only the means of constructing it. By the same token, public schools and government roads and dams are consumers' goods, even though such things are almost never purchased ready-built.

To be more exact, the definitions of capital goods and consumers' goods must be broadened as follows:

Capital goods are goods purchased for the purpose of making subsequent sales, and, by extension, goods produced, with means of production that have been purchased, for the purpose of making subsequent sales.

Consumers' goods are goods purchased *not* for the purpose of making subsequent sales, and, by extension, goods produced, with means of production that have been purchased, *not* for the purpose of making subsequent sales.

Thus both concepts embrace internally produced semi-finished and finished inventories and internally constructed facilities.

The definitions presented not only of capital goods and consumers' goods, but also of productive expenditure and consumption expenditure, producers' labor and consumers' labor, and producers' loans and consumers' loans, might be taken to imply the presence or absence of the purpose of earning *sales revenues exclusively* as the decisive point of differentiation. Such a restriction is not intended. Although sales revenues are the revenues earned in the overwhelming majority of cases, there are numerous and important instances in which businesses earn rental revenues—for example, landlords and car rental companies—or interest revenues, as is the case with banks and other financial institutions. Indeed, probably every business earns some interest revenue. There are also cases in which businesses earn royalty or commission revenues—for example, research laboratories and professional agents, respectively.

No less than in the case of sales revenues, it is the presence or absence of the purpose of earning revenues of these types that serves as the differentiating point. The words “subsequently selling” and “making subsequent sales” must be understood as embracing these kinds of revenues as well as sales revenues. The expenditures of a landlord for the purpose of earning rental revenues, of a bank for earning interest revenues, and so on, are productive expenditures. The goods they purchase for that purpose, the labor they employ, the loans they take out are capital goods, producers' labor, and producers' loans respectively.

Capital and Wealth

I have already defined capital as wealth reproductively employed.⁸ In a division-of-labor society, capital is *the wealth employed by business enterprises*.

There is, of course, wealth employed outside of business enterprises. Such wealth includes the houses and furnishings of individuals, their personal stocks of food and clothing, their automobiles and appliances, and so forth. It also includes a country's highways and dams and river and harbor improvements, insofar as they are owned

by the government, and all other assets owned by the government. Such wealth may be termed “consumers' wealth,” in contrast to capital, which is the wealth employed by business enterprises. So long as it is wealth, consumers' wealth has not yet been consumed, but it is in the process of being consumed. In the nature of the case, it is poised for being used up and its owner's purpose does not prepare it for making possible its own replacement. It is thus on the road to being consumed and is properly described as consumers' goods.

Jewelry, precious metals, and the land sites of owner-occupied houses usually represent a substratum of consumers' wealth which is not consumed beyond a certain point. To be sure, there is typically a maintenance cost which must be incurred in connection with all three—cleaning and repairing the jewelry, storing and insuring it and the precious metals, keeping up the appearance of the land site. But the materials from which the jewelry is made—gems and precious metals—are physically imperishable and always retain at least some substantial portion of their original value. Land sites too are physically imperishable (unless they become submerged under water), and so long as the area remains inhabited, they too almost always retain at least some substantial portion of their original value.

Capital Value and Investment

The goods owned both by business enterprises and by consumers reflect prior expenditures of money, either for the goods themselves or for the means of producing them. The prior expenditure reflected in the possession, say, of a quantity of roast beef that is owned either by a restaurant or a housewife is simply the price per pound that has been paid for it times the number of pounds in question. The prior expenditure reflected in the possession of a durable good, such as a washing machine owned either by a laundromat or a housewife, is the price that has been paid for it less a cumulative allowance for wear and tear and obsolescence known as depreciation. The prior expenditure reflected in the possession of a good one has produced or has had produced is the sum of the prices times the respective quantities of the means of production physically consumed to produce it, less, if it is a durable good, a cumulative allowance for depreciation.

For example, the prior expenditure reflected in an inventory of dresses in the possession of a dress manufacturer (or, as far as the items are applicable, in the possession of a housewife who makes her own clothes) would be the sum of the following, for each dress: the price paid per yard of cloth times the number of yards used up in making the dress, the wage rates paid to cutters and sewing machine operators and so forth times the

respective number of hours of their labor spent in making the dress, the prices—under some accounting systems—paid for the various tools and machines employed times the respective fractions of their useful lives expended in making the dress, plus all other sums similarly expended to make the dress. (Depending on the particular accounting system used, the prior expenditure reflected in the inventory of dresses might not incorporate an allowance for the fraction of the useful lives of the tools and machines expended. Such expenditures might show up simply in a cumulative periodic depreciation charge against the assets concerned and in a corresponding charge against sales revenues. This is even more likely to be the case in connection with depreciation accounting for a factory or any other kind of building used in a business.)

The prior expenditure reflected in the possession of goods—whether productive expenditure in the possession of capital goods, or consumption expenditure in the possession of consumers' goods—is known in accounting as their *book value*. This concept is of no practical importance for the ordinary consumer, but it is of great importance for business enterprises. It is the necessary base for calculating profits and losses. For example, to have a profit, the dress manufacturer must sell his dresses for more than their book value and the depreciation charged against the book value of the factory and plant and equipment used to produce the dresses (insofar as this depreciation does not enter into the book value of the dresses themselves). The concept of book value is the basis of constructing both balance sheets and income statements.

Book value can be said to reflect a putting of money into goods. The putting of money into goods for the purpose of making subsequent sales is *investment*. The book value of any aggregate of goods in which money has been invested, i.e., of capital goods, is the book value of capital, that is, of wealth reproductively employed.⁹ Under a system of commodity money, such as a gold standard in which physical gold serves as actual money in the form of coins passing from hand to hand or coins or bullion providing full backing for the paper currency or checking deposits in use, the concept of capital would also include the money held by business enterprises. This is because in such a case the money would be both actual wealth, inasmuch as it was a physical commodity, and it would be reproductively employed. As wealth reproductively employed, it would be capital.

Now just as the concept of property possessing market value was shown to be wider than the concept of wealth, so the concept of capital value refers to more than the value of wealth reproductively employed, that is, to more than the value of capital goods or capital.¹⁰ By the same token, the concept of investment refers to more than

investment in capital goods. The concepts of investment and capital value also respectively refer to investment in, and the accompanying purchase or acquisition value of, such intangible assets as stocks and bonds, mortgages and other types of loans, and patents and copyrights. One can invest in such intangible assets, and their purchase or acquisition value constitutes capital value.

Nevertheless, intangible assets no more constitute capital than they constitute wealth. Investment in *capital* occurs only when business enterprises buy either tangible goods or labor of the kind that is vested in tangible goods. (Of course, such investment is carried forward when capital goods are productively physically consumed, to the products produced—for example, the dress manufacturer's investment in cloth is carried forward to the dresses made out of the cloth.) The value of capital is the value of the tangible goods purchased by or produced within business enterprises, plus, insofar as it itself constitutes actual wealth, the money they hold. It is, to this extent, their cash and the value of their raw, semifinished, and finished inventories, of their furniture and fixtures, plant, equipment, and all other tangible property, including, of course, their land. The objective expression of the value of these capital assets is their accounting book value, which derives from their purchase prices.

In the following pages of this book, whenever investment is spoken of, it should be understood that in the absence of qualification, what is meant is always investment in *capital*.

The most important respect in which capital value in the economic system differs from the value of actual capital goods is the result of the use of savings to finance such things as home mortgages and consumer installment loans. Because owner-occupied housing and personal automobiles and the like are not capital goods, the mortgage loans and installment loans that finance them, while representing investment and the existence of capital value from the perspective of the lenders, do not represent investment in capital goods. Such investments, to be sure, represent a significant part of the total savings and capital value of the economic system.

Matters are complicated somewhat by the use of the expression "investment of *capital*" to signify the purchase of such assets. Insofar as the money invested were itself a physical commodity and thus represented wealth reproductively employed in being invested, the expression would be a perfectly legitimate one, though it would still be necessary to realize that what the capital had been invested in, in such cases would not itself represent capital, but only intangible assets possessing capital value. Of course, today money is not a physical commodity; it is not even in part a claim to a physical commodity.

Nevertheless, common usage regards the investment of fiat money as the investment of capital. For the sake of avoiding departures from common usage that would serve little practical purpose, I will follow it, even though what is being invested in the case of fiat money is not actual wealth, but at most an intangible asset that can easily be exchanged for wealth.

Consistent with this discussion, I follow the common practice of regarding anyone who invests money in intangible assets as a capitalist, even though such assets do not themselves represent actual capital but merely possess capital value. Insofar as such capital value represents the financing of the purchase of consumers' wealth, such as homes and personal automobiles, I will take it into account whenever necessary in close connection with my treatment of the degree of capital intensiveness of the economic system. For the accumulated savings of the economic system are invested not only in capital but also in intangible assets, above all, home-mortgage loans, which represent claims against consumers' wealth.¹¹

It would be possible to adopt a somewhat different approach to the meaning of investment than that taken above. It could be argued that all putting of money into goods is investment, whether the purpose is or is not to make subsequent sales. In this case, it would be necessary to distinguish between productive and unproductive investment. One would then show the derivation of capital from productive investment, and consumers' wealth from unproductive investment.

The objection I have to this approach is that it would shatter the customary distinction between consumption and investment. Perhaps half or even more of consumption expenditure would then turn out to be investment expenditure, at the same time that it was consumption expenditure. This is because under such a procedure, the purchase of houses, automobiles, and all other consumer durable goods would have to be classified as investment expenditures. So too would the purchase of materials of production by consumers, such as all food needing further preparation.

Thus, it seems expedient to restrict the concept of investment in the way I have done, and not to introduce the concept of unproductive investment.

Productive Expenditure and Capital Value

While capital value reflects prior productive expenditure, not all productive expenditure results in capital value, because not all productive expenditure is invested. Productive expenditure for such things as advertising, lighting and heating, and the labor of administrative and clerical employees does not directly bring any tangible physical goods into the possession of a firm. Such things

are neither tangible goods themselves, nor in any direct way are they vested in tangible goods, in the manner of the cloth and the services of a sewing machine operator that go into a dress. As a result, it is a common practice in accounting to treat such productive expenditures as *expense items*. That is, such productive expenditures are written off—expensed—as they are made, and thus do not show up in capital value.

Some accounting systems, however, seek to capitalize as many productive expenditures as possible, and do add the outlays for advertising, lighting and heating, administrative labor, and so forth to a firm's capital value, if possible in the form of its investment in inventory. The outlays are then subtracted later on, typically when the goods to which they are judged to contribute are sold. At that time, the outlays form a part of "cost of goods sold"—along with the outlays for materials and direct, manufacturing labor and, in some cases, along with depreciation.

Common Confusions About Capital Goods

There are three currently popular definitions of capital goods. All of them are physicalistic, i.e., assume that the distinguishing characteristic of capital goods lies either in their physical nature or in their relationship to physical production. According to what is perhaps the definition most favored among professional economists, capital goods are tools, implements, machinery, and durable goods. According to what seems to be the most popular definition among laymen, capital goods are the same as the above, but with the durable goods more or less limited to factory and office buildings. According to the third definition, capital goods are all previously produced factors of production, which would include the materials employed in production along with the components of the layman's definition.

Like the misconceptions concerning productive activity in general, these definitions are both too broad and too narrow. They are too broad in that they all embrace consumers' goods to varying degrees, and too narrow in that they fail to embrace many capital goods.

Those who hold these definitions seem strangely unaware in propounding them that production in its physical sense is almost an omnipresent phenomenon, and is undertaken by consumers with the aid of means of production that in principle, and sometimes in actual concretes, are no different than those employed in any factory. Strictly speaking, it is an act of physical production when one cuts the food on one's plate and raises it to one's mouth on the prongs of a fork. As already discussed, the activities of a housewife constitute acts of physical production. Certainly, cooking, cleaning, washing, baking, and, a few generations ago, the making even of clothes

and soap in the home, are all instances of physical production.

And this production, no less than the production that takes place in giant factories, entails the use of materials, tools, implements, machinery, buildings, and other installations. The food in one's refrigerator is a material—indeed, so is a slice of bread in one's hand which one intends to butter. Household hammers and screwdrivers are tools; can openers, knives, and forks are implements; sewing machines, washing machines, automobiles, vacuum cleaners, toasters, television sets, tape recorders, and record players are machines; the home, in which so much physically productive activity takes place, is a building employed in production; a wash line is an installation. Indeed, there are very few consumers' goods which do not fit under these or other categories connected with physical production. And the few that do not fit, such as stocks of clothing and certain types of furniture and fixtures owned by consumers, are almost all embraced by the category of durable goods.

All three of these definitions, as soon as they are accompanied by any attempt to apply them to reality, lead to a progressive reduction in the goods classified as consumers' goods and a progressive increase in the goods classified as capital goods. Indeed, this change in classification is well under way.

It has long since, if not always, been taken for granted that government river and harbor improvements and the pieces of construction equipment owned by a government are capital goods, simply because their connection with physical production is so obvious. What has prevented the less spectacular means of production that are found in the home from being classified as capital goods seems to be only the fact that the classical economists succeeded in fairly well establishing the idea that housewives do not produce.

Of course, in recent generations, this last idea has come to be held in an erroneous way. Instead of having the conscious realization that housewives do not produce only in the sense that they do not earn money, and why this fact is decisive, one proceeds as though housewives did not produce even in the physical sense. This then acts as a sort of blinders, which prevent one from perceiving the kind of physical means of production housewives employ. Furthermore, in the present day, the idea that housewives do not produce is widely disputed. For example, it is often presented as a shortcoming of the statistics of gross national product, or gross domestic product, that they do not include an allowance for the work performed by housewives in the home.

The stage is well set, therefore, for a "revolution" in economics on this subject. That is, at practically any moment someone could come along, write a book or

article forcefully making people aware that housewives do physically produce and employ machinery and the like, and then, without a knowledge on anyone's part that the earning of money is the crucial criterion, succeed in almost totally destroying the concept of consumers' goods by discovering that they are all "capital goods."

For the time being at least, the physically productive activities of the housewife and the physical nature of the goods she employs have not sufficiently impressed themselves on the minds of observers. As a result, the main breaches in the concepts of consumers' goods and capital goods have been in the somewhat related areas of durable goods and government activity.

Nonprofit universities refer to their building funds as "capital funds." Government officials wish to remove expenditures for roads, schools, dams, and the like from the ordinary budget and place them in a separate "capital budget." (This has long been the practice in New York City, for example.) Government statistics of gross product and national income treat the purchase of houses to be occupied by their owners as "investment." Few economists see any theoretical reason why the treatment now accorded to owner-occupied houses in these statistics should not be extended to personal automobiles, household furniture, and all major household appliances. The more consistent wish to add stocks of personal clothing to the list. Only the weakening forces of custom and tradition, established by the classical economists, stand in the way of a major collapse in classification here.

The belief that the government employs capital goods has been greatly reinforced both by the inclusion of durable goods in the concept of capital goods and by what must be called an eagerness to perceive in its case the fact that it is physically productive. And the idea that the government employs capital goods then lends strong support to the notion that it is a producer. If, for example, a government schoolhouse is a capital good, then it follows naturally that government school teachers must be productive in the same sense as was previously thought to be reserved to the participants in private business.

Indeed, we have been told that to deny the proposition that government officials are productive, to hold instead that their salaries and their activities simply represent consumption, is to labor under the influence of a collection of old wives' tales known as "the conventional wisdom."¹² Not surprisingly we have also been told from the same quarter, that there is no essential difference between government deficits and corporate "deficits"—i.e., between consumers' loans and producers' loans.

The current concepts of capital goods, however, are not merely overblown, to the point where they destroy any firm concept of consumers' goods. As stated, they also do not even embrace all capital goods. The first two

definitions I cited ignore materials, which certainly must be included when purchased by business enterprises. The second and third appear to ignore such goods as furniture and fixtures, because they are not integrally connected with physical production, but which must be termed capital goods when purchased by business enterprises. All three leave no room for finished inventories, which are also capital goods when owned by business enterprises, despite the fact that they do not serve in any further physical production undertaken by the firms that own them, or, perhaps, in any further physical production whatever.

Answers to Misconceptions of the Concepts Presented

A number of questions frequently arise concerning the application of the concepts presented to specific cases—questions which reflect serious misconceptions of the concepts. The nature of the misconceptions, the questions, and the answers to them, are as follows:

i. Productive Consequences of Consumption Do Not Make Consumption Into Production

It is a fact that if a person did not eat some minimum amount of food, wear at least some kind of clothing, and have some type of shelter in which to sleep, he could not physically work and thus could not earn money. On this basis, the question is asked: Shouldn't the expenditure for such goods, to the extent that they contribute to one's ability to work and earn money, be termed a productive expenditure, and such goods themselves, capital goods?

The answer is no. In order for any action to be productive, either monetarily or physically, it is not sufficient that the action have productive consequences. The action must be undertaken for the *purpose* of production. For example, in driving one's car, one wears it out. Eventually, as a result of one's action, it will be scrap iron, and then it will most likely contribute to the production of steel. Nevertheless, this fact does not make one a steel producer. It does not make one's expenditure for the car a productive expenditure and the car a capital good. The scrap iron, even though the result of the process of driving one's car, is not the *product* of driving one's car. It is a fresh, original, *unproduced* factor of production, just like iron ore in the ground. In the same way, the fact that eating, wearing clothing, and possessing a shelter result in one's being alive, and thus capable of working and earning an income, is not sufficient to render these things acts of production. Like the scrap iron, a person's ability to work, based on the fact that he is alive, is a fresh, original, unproduced factor of production, not a product.

The decisive point in establishing whether an expenditure is a productive expenditure, or whether a good is

a capital good, is the *purpose* for which the expenditure is made or the good bought, not the consequences it has. Food, clothing, shelter, and the like are consumers' goods, and the expenditure for them a consumption expenditure, even insofar as their consequence is an ability to work and earn money—because working and earning money are not their purpose. On the contrary, the ability to buy such goods is the purpose of working and earning money.

The essential point can be reinforced by the following considerations. If it were the case that expenditures for the goods and services necessary to enable one to stay alive and thus be able to work were regarded as productive expenditures, the effect would be that one would have to deduct these expenditures as costs from the income one earned as normally understood. One would then regard one's net income—the measure of one's gain from working—as the difference between one's income as normally understood and the cost of one's subsistence. Thus, for example, if a wage earner makes, say, \$300 per week, and his cost of "subsistence" is calculated as \$200 per week, he would calculate his net income—the measure of his gain from working—as \$100 per week. This shows the fallacy of the whole procedure. The fact that of the worker's \$300 wage, \$200 is necessary to cover the cost of his subsistence, does not at all reduce his gain from working from \$300 to \$100. His gain from working is \$300. *The greatest, most important part of a person's gain from working is that it enables him to stay alive.* A worker who works even to receive merely a subsistence wage has an enormous gain from his work: he gains the preservation of his life, a value greater than which there is none. The fact that the portion of one's wage that covers subsistence is itself a gain—the most important gain one earns—means that it is inappropriate to deduct subsistence as a cost. And on this basis it is inappropriate to regard the expenditures for the means of subsistence as productive expenditures, even though they are essential to one's ability to work. Their purpose is not the earning of income, but the support of one's life.

ii. Consumption Expenditures Imposed by Work Are Still Consumption Expenditures

A second, closely related question is this: Isn't a maid employed by a working mother to look after a young child an instance of producers' labor, in that the mother could not go to work and thus could not earn money if she did not employ the maid?

Again, the answer is no. The mother does not employ the maid for the purpose of earning money, but for the purpose of meeting a need of her personal life—namely, caring for her child. To be sure, she is unable to meet this need herself as a result of the fact that she leaves the house to go to work, but that is irrelevant. Earning an

income does not take place in a vacuum. It is integrated into the rest of one's life, and compels a person to meet certain of his needs or desires by making expenditures he would not have to make if he did not have to earn an income. For example, many people who work, automatically have a higher food bill because they have to eat their lunches out. They probably have a transportation expense of getting to and from work. Possibly their work requires that they live in an area which has a cold climate, and in which, therefore, they must buy extra winter clothing and pay high fuel bills.

Though all of these expenditures are *imposed* by the earning of an income, they are still consumption expenditures, because their purpose is the direct satisfaction of one's needs or desires, not the earning of money. The working mother does not employ a maid to make money, any more than the man who must eat his lunches out because he works, eats out to make money. The commuter on the way to work does not pay his fare to make money, but because he wants to avoid walking, or to be able to live in the suburbs, just as the man whose job is in a cold area does not buy extra winter clothing or pay high fuel bills to make money, but to keep warm.

*iii. A Smaller Consumption Expenditure
Is Still a Consumption Expenditure*

A third frequently asked question is this: In view of the fact that the purchase of a house typically means a saving of expense in comparison with renting, shouldn't it, for this reason, be considered a productive expenditure, and the house itself, a capital good? Likewise, if the purchase of a washing machine by a housewife makes it possible for her family to reduce its expense for laundry, shouldn't the expenditure for the washing machine be considered a productive expenditure and the washing machine itself, a capital good?

Once more, the answer is no. These questions rest on the idea that the saving of a consumption expenditure is a source of income. The saving on rent or laundry is supposed to be an extra income which the purchase of the house or washing machine brings in and which makes that purchase a productive expenditure and the house or washing machine a capital good.

The saving of a consumption expenditure, however, is not a source of income. It simply means that a smaller consumption expenditure takes the place of a larger one. The smaller consumption expenditure is still a consumption expenditure. And thus the conclusion contained in the question is false. If, for example, a person buys a house and has a monthly expense of \$1,000 for mortgage payment, fuel, repairs, and the like, instead of, say, a \$1,200-per-month rent bill for comparable living quarters, it is not true that his income is thereby increased by

\$200 per month. What is true is that instead of consuming \$1,200 per month for shelter, he now consumes \$1,000 per month for shelter—in addition to having expended his down payment on the house for consumption. The \$1,000 per month and the down payment are consumed because the house does not bring in any money revenue. It physically depreciates and must be maintained and eventually replaced by funds supplied from outside sources. Both the house and what is spent for it are simply used up and gone—consumed. In exactly the same way, if the purchase of a washing machine enables a family to reduce its expense for laundry from, say, an average of \$20 per week to an average of \$10 per week, what has occurred is that the family now consumes \$10 per week for laundry instead of \$20 per week. For its outlays, too, do not make possible the means of their being repeated, but depend on an outside source of funds for their continuation, and thus represent consumption. The case is exactly the same in principle as if the family had simply found a lower-priced laundry.

It is true that a reduction in consumption expense allows any given, *already existing* money income to go further. In this respect it achieves the equivalent of a rise in income in terms of *buying power* (assuming, of course, that what the reduced expenditure buys really is the equivalent of what the larger expenditure bought before). But the reduced expenditure does not itself bring in any income. Its ability to achieve the equivalent of a rise in income in terms of buying power presupposes the existence of an income *which it itself does not bring in*. A correct description of things would be to say that while the ability to obtain equal satisfactions for a reduced expenditure of money achieves the equivalent of a rise in income in terms of buying power—assuming that an income already exists—the reduced expenditure itself is still a consumption expenditure.

The idea that a reduction in consumption is the earning of income totally perverts the meaning of consumption by making it into its exact opposite. It seeks to wipe out the difference between spending money and making it; as though because one tended to use up one's funds and grow poorer less rapidly, one thereby earned funds and grew richer.

The difference between consumption expenditures and productive expenditures can be seen precisely in terms of the profound difference that exists in the respective ways in which they contribute to buying power. The only way that consumption expenditures can contribute to buying power is through their *reduction*, i.e., through their comparative nonexistence, not through their positive presence. Their positive presence is always merely a using up of buying power provided by other sources.

Productive expenditures, on the other hand, contrib-

ute to buying power through their positive presence, for it is their positive presence that brings in revenue and income. This is no less true in cases in which reductions take place in the productive expenditures required to produce a given product—i.e., in which the production of the product becomes more efficient and thus less costly. The reduced productive expenditures to make that product bring in sales revenues and are made for that purpose, and using the funds saved in producing that particular product to make other productive expenditures will now bring in still more sales revenues. Thus, for example, if a home builder or washing machine manufacturer finds a way to reduce his unit costs, his lesser outlays are still the source of his revenues and are still made for the purpose of bringing in those revenues, and if he devotes the savings in his outlays to fresh productive expenditures—in increasing his production of homes or washing machines or in branching into different lines of business—his sales revenues will further increase.¹³

Thus, consumption remains consumption, even when it is carried on in a more economical fashion.¹⁴

*iv. Government Expenditure Is Consumption
Expenditure Even When It Serves to Increase the
Capacity of the Citizens to Pay Taxes*

Certain government expenditures, such as for highways and education, if not made with the grossest inefficiency, have the potential for contributing to the productive capabilities of the citizens, and thus to their ability to work, earn income, and pay taxes. On this basis, the question is sometimes asked if such government expenditures could not be construed as productive expenditures—at least if the expenditures were made by the government for the purpose of bringing in tax revenues.

The answer is no, even in the event that the government really did make expenditures for the purpose of increasing the tax base and thus its tax revenues. So long as the highways are not self-supporting toll roads, so long as the education is provided for free or at only a nominal charge, the activities represent consumption. The very fact that taxes must be resorted to in order to support them fully confirms this fact. Taxes are not a revenue earned in production and exchange. They are not paid in exchange for the use of roads or for instruction—i.e., as the condition of receiving these things. What actually brings about their payment is the threat of being imprisoned if one does not pay them.

In providing such things as highways and education for free, the government is as much a consumer as would be a private individual who had the peculiar habit, let us imagine, of making gifts of encyclopedias to bright children. His gifts could well increase the capacity of the recipients later on to work and earn money. But the gifts

would still leave him that much poorer. For him, they would still be consumption. Nothing would be changed if this individual combined his habit of gift giving with a program of systematic burglaries carried out against victims who had first been fattened up, so to speak, by the receipt of such gifts—victims whose capacity to earn incomes and thus to yield more ample caches to burglars was increased by the gifts. (The analogy is accurate insofar as the government's collection of taxes constitutes the appropriation of property against the will of its owners.)

To put the matter as succinctly as possible, the government is no less a consumer, merely because its activities have the effect of increasing the ability of the citizens to pay taxes and thus to support its consumption.

Similar considerations apply to the classification of government employees engaged in the collection of taxes. Such employees are not to be classified as producers' labor even though their work directly serves to bring in money to the government. So long as taxes are collected under the threat of physical force for nonpayment, they cannot be described as the result of any kind of productive activity on the part of the government or its agents. They are obtained as the result of coercion pure and simple. In such circumstances, the concepts of production, productive expenditure, and producers' labor simply do not apply. They are no more applicable than is the concept of capital goods to burglary tools, which also very likely serve to bring in more money than they cost. Consistent with what I have already pointed out, all concepts pertaining to production and productive activity of any sort preclude the obtaining of wealth by means of force. Expenditures made for the purpose of carrying out the use of force belong in a separate, third category, that is neither productive expenditure nor ordinary consumption expenditure—namely, that of *destructive* expenditure. True enough, when such expenditure is made for the purpose of bringing in money, the funds of the perpetrator are not decreased, but the funds of the victims certainly are. Moreover, to the degree that such expenditures exist and serve to victimize people, the effect is to diminish the incentives and the means for producing wealth. Thus the gains of the perpetrators result in more than equivalent losses to others. This is obviously a process far more at odds with the preservation and increase of wealth than is consumption.

In a very different, but nevertheless related vein, workers employed as part of a charity organization's fund-raising efforts are to be classified as consumers' labor rather than producers' labor, despite the fact that money is brought in by their activities. This is because the money brought in is charitable donations, not pay-

ments made in exchange for the receipt of goods or services. The payment of the salaries of such employees no more represents a productive expenditure than does a student's payment for the stationary on which he writes letters to his parents asking for money. The expenditure in both cases is a consumption expenditure which, fortunately for those who make it, is as a rule substantially more than defrayed by the charity of the recipients of the appeal.

Of course, the workers who are employed by a charity, whether as fund raisers or in any other capacity, are themselves productive in the sense appropriate to life in a division-of-labor society, inasmuch as they earn money. However, they earn money as consumers' labor, not as producers' labor.

v. "*Human Capital*" Is Not Capital

The last question to be considered here primarily concerns education. Is education, and other improvements in people's personal capacities that enable them to produce more efficiently and thus to earn a higher income, a form of capital? Is it, as many economists describe it, "human capital"?

If an education is obtained for the purpose of earning money, as is the case with vocational education, then the expenditure could, indeed, plausibly be termed a productive expenditure. Nevertheless, the fact that as productive expenditures, the outlays would have to be deducted as costs from wage incomes leads me to conclude that they should still be treated as consumption expenditures. This is because treating them as productive expenditures, which give rise to costs, would in turn require thinking of wages as analogous to sales revenues and having to regard the income of wage earners as a form of profits earned on the receipt of wages. That is to say, that merely because they had paid something in order to learn their trade, one would suddenly have to regard carpenters, plumbers, electricians, and the like as earning profits on their wages rather than as simply earning wages. At the same time, such productive expenditures and costs would have absolutely no bearing on the amount or rate of profit earned by actual businesses. Thus, radical conceptual change would be required in order to deal with a relatively small set of concretes, which concretes would have no bearing on the amount or rate of profit that is of actual concern. To avoid such a fruitless procedure, it is far simpler for all practical purposes to regard such productive expenditures of wage earners as consumption expenditures. The only exceptions should be cases in which the individuals involved actually do function as businesses, such as champion professional athletes who employ trainers and coaches and the like, and whose incomes really can be regarded as profits earned on business sales revenues.

Beyond this, even if one were to regard such expen-

ditures as productive expenditures, it would still be an error to consider improvements in an individual's personal capacities to be a form of capital or any other kind of wealth. They are preconditions to the production of wealth or to the greater production of wealth, but not themselves wealth.¹⁵ An essential characteristic of wealth in general, and of capital in particular, is its *alienability*. The possession of wealth and capital makes it possible for an individual to live without having currently to exercise his productive abilities—to live by means of selling off part of his wealth or capital and consuming the proceeds. It is not possible to do this with so-called capital that is part of one's very person. Such "capital" is inseparable from one's person and thus cannot be sold off. In this respect it differs radically from wealth and capital, and should not be placed in the same category.

The concept "human capital" would overcome this objection in a society that sanctioned slavery. A slave owner could regard greater personal capacities in his slaves as representing additional capital to him. But even then the concept of human capital would be improper—not only on all the grounds that make slavery improper, but also on the specifically economic grounds that neither human labor nor the persons of human beings constitute wealth.¹⁶ And since capital is a specific form of wealth, they do not constitute capital. Indeed, as I have stated before, slavery is an institution hostile to the production of wealth by virtue of depriving the slaves of the incentive to produce it. And because of this, slavery is also hostile to the formation of capital. This last will become clear after I have shown that capital accumulation depends on all the factors that promote the production of wealth in general.¹⁷

In addition, there is a further major and specifically economic objection to the concept of human capital in the form of slaves. This is the fact that a society that sanctions capital in the form of the existence of other human beings thereby deprives itself of capital in the true sense of wealth reproductively employed. Such immoral and fictitious capital *displaces* actual capital. This is because people want to possess capital in some determinate ratio to their level of consumption, not in an infinite ratio. Thus to the extent that they think themselves rich on the basis of the ownership of slaves—which means that they think themselves rich merely because of the existence of workers—they feel no need to accumulate and possess genuine capital, that is, capital in the form of actual wealth. As illustration of the consequences, consider the difference in conditions between the North and South prior to the Civil War. A Northern manufacturer regarded his capital as his factory and machines, and his inventory of materials and finished products. He did not count as any part of his capital the persons of his

employees. The Southern plantation owner, on the other hand, considered himself rich by virtue of the mere presence of his workers, who were his slaves. Thus he did not consider it necessary to accumulate substantial capital in the form of nonhuman means of production, because he thought he already had capital—in the possession of his slaves. The institution of slavery thus operated to deprive the South of the accumulation of actual capital, because people believed that their ownership of other people constituted their capital. The results of this deprivation of actual capital in the antebellum period contributed to the South lagging far behind the North in economic development for generations to come.

Adam Smith on “Productive and Unproductive Labor”

It is appropriate to acknowledge here the contribution of Adam Smith to the grasp of the essential connection between productive activity and moneymaking and the decisive role this connection plays in the distinction between production and consumption. To be sure, Smith commits the error of holding that in order for an activity to be productive, it must produce tangible physical goods, as though that were essential to its earning of money. He also made the error of including acquired personal abilities in the concept of capital.¹⁸ In the very passages in which he makes the error of holding the need for the production of a tangible physical good, however, the essential role of moneymaking, as enabling the activity to be self-sustaining and a source of profit stands forth very clearly. It is worth quoting him:

There is one sort of labour which adds to the value of the subject upon which it is bestowed: there is another which has no such effect. The former, as it produces a value, may be called productive; the latter, unproductive labour. Thus the labour of a manufacturer adds, generally, to the value of the materials which he works upon, that of his own maintenance, and that of his master’s profit. The labour of a menial servant, on the contrary, adds to the value of nothing. *Though the manufacturer has his wages advanced to him by his master, he, in reality, costs him no expense, the value of those wages being generally restored, together with a profit, in the improved value of the subject upon which his labour is bestowed. But the maintenance of a menial servant never is restored. A man grows rich by employing a multitude of manufacturers: he grows poor by employing a multitude of menial servants.*¹⁹

And, very importantly, in regard to the activities of government:

The labour of some of the most respectable orders in the society is, like that of menial servants, unproductive of any value, and does not fix or realize itself in any permanent subject, or vendible commodity, which endures after that labor is past, and for which an equal quantity of labour could afterwards be procured. The sovereign, for example, with all the officers both of justice and war who serve under

him, the whole army and navy, are unproductive labourers. They are the servants of the public, and are maintained by a part of the annual produce of the industry of other people. Their service, how honourable, how useful, or how necessary soever, produces *nothing for which an equal quantity of service can afterwards be procured. The protection, security, and defence of the commonwealth, the effect of their labour this year, will not purchase its protection, security, and defence for the year to come.*²⁰

Smith did not realize that the labor of “menial servants” can contribute to the earning of revenue by their employer, and thus to the subsequent payment of their wages. This is the case, for example, with the employment of maids by a hotel or waiters by a restaurant. Nor did he realize that the employment of “manufacturers”—workers producing tangible physical goods—need not always be a source of revenue to their employer. It is not in such cases as workers employed in a shipyard owned by the navy.²¹ For the same reasons, he did not see that an employer can increase his wealth by the employment of “menial servants” and consume his wealth in the employment of “manufacturers.”²² He did not see that the question of whether or not tangible physical goods are produced is simply irrelevant to the question of whether labor should be classified—in our terminology—as producers’ labor or as consumers’ labor.

Nevertheless, in comparison with his grasp of fundamental truths in connection with the tie of productive activity to moneymaking, Smith’s errors are relatively minor, and do not significantly detract from the value of his accomplishments. Sadly, however, Smith’s contributions here are almost completely overlooked nowadays. This is only in part because of his confusion concerning the need for the production of a tangible physical good to qualify an activity as productive. The main reason, I will show, has to do with the much more important matters discussed in Part C of this chapter.²³

5. Critique of the Concept of Imputed Income

The concepts of income and cost pertain to receipts and outlays of money. As the preceding section made clear, this essential fact can easily be overlooked. For example, this was the case when one regarded the saving of an expenditure—the absence of a cost—in the purchase of a home or washing machine as the earning of an income.²⁴ For many years, I myself overlooked the essential connection of income and cost with the receipt and expenditure of money. I did so until I became aware of the requirements of explaining aggregate profit in the economic system as an excess of the money sales revenues of business over the money outlays of business that later on show up as costs deducted from the sales revenues. Solving the problem of how business in the aggre-

gate could regularly and consistently sell for more money than it bought placed me under the necessity of looking for a *monetary source* of the surplus and of focusing on matters for the first time strictly in terms of money outlays and money revenues. When I saw the fruitfulness of this approach, I began to recognize the great importance of not confusing actual receipts and outlays of money with any form of fictional outlays and receipts of money.²⁵

Contemporary economics, in contrast, continually ignores the vital connection of income and cost with the receipt and outlay of money. It does so insofar as it propounds the doctrines of “imputed income” and “opportunity cost.”²⁶ The doctrine of imputed income openly and systematically avows that the absence of a cost constitutes income. The doctrine of opportunity cost, on the other hand, holds that the absence of an income constitutes a cost. Contemporary economics thus deals in nonexistent incomes and costs, which it treats as though they existed. Its formula is that money not spent is money earned, and that money not earned is money spent.

As I have indicated, these doctrines stand in the way of developing an understanding of the determinants of aggregate profit and the average rate of profit in the economic system. In addition, they turn out to be riddled with contradictions and absurdities.

I have already described the procedure of the imputed-income doctrine in some detail in the case of owner-occupied housing. This procedure is explicitly and officially endorsed by the U.S. government in its compilation of statistics of national income and gross national product. The rationale for the procedure is to be able to perform an alleged measurement of production which would otherwise be omitted from the statistics. In the words of an official U.S. government publication:

The imputation for the rental value of owner-occupied homes is made to provide comparable treatment between rented and owner-occupied housing. It assumes that home ownership is a business producing housing services which are sold to the homeowner in his capacity as tenant. These sales are estimated in terms of the sum for which the particular type of home could be rented, and the expenses of the home owners are deducted to obtain imputed net rent. The imputed gross total becomes a part of sales to persons, or consumer expenditures, and imputed net rent becomes a part of the rental income of persons.²⁷

To make clear the meaning of this quotation, we need only recall the example I presented of the individual who instead of renting a house for \$1,200 a month buys a comparable house and incurs monthly expenses of \$1,000 in keeping it up. The homeowner’s \$200 a month saving of expense is treated as a \$200 increase in his monthly income. The only difference between the government’s procedure and that of my example is that the government’s procedure counts the depreciation on the house in the

homeowner’s costs rather than any repayment of principal on the mortgage, which is appropriate if one holds the bizarre context.

The nature of the government’s procedure and all the twists and turns it involves can be grasped by taking seriously the claim that a homeowner has an additional income of \$2,400 per year by virtue of owning his home and thereby saving an expense of \$200 a month in comparison with renting. If this claim is taken seriously, the question immediately arises of what has become of this \$2,400 of alleged additional income? If it has been received as income, it must show up either as an addition to the individual’s consumption expenditure or to his savings or, in some measure, to both. But where is it? For his consumption expenditure and the change in his savings add up only to his income in the normal sense of money actually received or due. The “solution” is to claim that not only does the homeowner receive \$2,400 per year in income he doesn’t receive, but that he also consumes this \$2,400 per year in paying—to himself—the very rent he was originally supposed to be spared! He does not and yet simultaneously does, it is alleged, incur \$200 per month of housing expense.

This “solution,” when worked out in detail, entails a whole host of fictions and contradictions. The first is that the \$1,200 which, by the very conditions of the case, are not paid in rent, are paid in rent. They are allegedly paid in rent by the homeowner to himself. This gives rise to the further fiction that the homeowner is a landlord, and that he is so precisely in a respect in which he cannot be—namely, with regard to the house which he himself occupies and which he therefore withholds from the rental market. From the fiction that the homeowner is a landlord follows the still further fiction that his \$1,000 monthly expense for mortgage interest and so forth is a business expense, and thus the still further contradiction that a nonbusiness expense is a business expense. It is by subtracting this nonbusiness business expense of \$1,000 from the nonrental rental, nonrevenue revenue of \$1,200 that the nonincome income of \$200 per month is arrived at, which is allegedly consumed in housing expense in contradiction of the fact that by the nature of the case this \$200 is not consumed in housing expense. And, as one last touch of the absurd, this phantom income of \$200 is raised to the status of a phantom who is his own grandfather. There could be no phantom income of \$200 if there were no phantom revenue of \$200 in excess of the phantom business expense. This extra phantom revenue, however, can only exist if there is first a phantom consumption of \$200. But there can be no phantom consumption of \$200 unless there is first a phantom income of \$200. But, of course, in dealing with phantoms, one need not quarrel over any contradictions in the order of their descent.

The absurdities to which the doctrine of imputed income leads in the effort to measure production that is not brought to market are limited only by the extent of its application. Thus, if one applies it to housewives, and asks how much a man would have to pay to obtain from the market the same services his wife provides for free, one can easily come to the startling conclusion that the income attributable to the average housewife is higher than the income of her husband, despite the fact that she does not earn an income, while he does.

The application of the imputed-income doctrine to the services of housewives is frequently advocated by textbooks dealing with “macroeconomics.” They typically consider it a deficiency of the gross product statistics (GNP or now GDP) that the statistics do not allow for the value of services performed in the home. For example, Samuelson and Nordhaus write: “Consider also do-it-yourself work done in the home—cooking meals or insulating walls. Because the values added are not bought or sold in markets, they never enter into the goods and services of the GNP An estimate of NEW [“net economic welfare”] will need to include the value of similar do-it-yourself activities.”²⁸

An imputed value of housewives’ services was actually calculated by a major New York City bank in the 1960s, which arrived at a figure that exceeded the income of the average working husband. The bank made its calculation by applying the wage rates of cooks, housekeepers, chauffeurs, maids, governesses, nurses, and so forth to the hours the average housewife is supposed to spend in each of these respective activities, and then adding up the result. (Much more recently, in 1992, legislation was proposed in Congress to compel the Department of Commerce to include such an allowance in the calculation of gross domestic product. Inclusion would reportedly add \$1.46 trillion a year to the GDP.²⁹)

If one were to ask how the average husband is supposed to be able to pay for these services that are allegedly beyond his income, one would be driven to the counterbalancing absurdity that the average housewife supports her husband—she turns over to him her earnings in these capacities so that he may be able to buy her services from her. This bookkeeping procedure accords perfectly with that which is used in the case of the imputation for owner-occupied housing, in which the imputed income is allegedly used to finance the alleged additional consumption that makes its own alleged existence possible. Here the wife’s imputed income finances the husband’s alleged additional consumption.

Curiously, the devotees of the imputed-income doctrine omit an imputed value of the wife’s *sexual* services from their calculations. Were they to include it, they would no doubt discover that her income exceeds her

husband’s by an even more substantial margin, for the prices of call girls’ services are much higher than those of cooks and housekeepers, and so forth. And on a national basis, the national income and gross domestic product of the country would most likely be doubled at least, with sex emerging as far and away the nation’s largest industry, and sexual intercourse as the most important component of the index of industrial production, which economists might then follow with far more rapt attention than they do the output of steel and automobiles. Though logical consistency requires such an imputation, it has not been attempted or even suggested. The supporters of the imputed-income doctrine are willing to regard wives as interchangeable with hired cooks and housekeepers and thus to obliterate the nature of marriage in this respect, but they are unwilling to go the whole route and claim that wives are prostitutes—and husbands their customers, enabled to afford their services by living off the proceeds of their wives’ prostitution.

When applied in the attempt to measure “net economic welfare,” the doctrine of imputed income can easily make beggars into millionaires. Consider the expenses one saves by not being blind and thus not having to hire a nurse, or by virtue of not having cancer, or not needing a psychiatrist. When such savings are added to a person’s income, in the attempt to measure his economic welfare, he can easily turn out to “earn” \$100,000 a year—even though he may not be able to afford to *buy* a cup of coffee.

Consider how easy it is to raise one’s income when it consists of such fictions. A wife who buys a \$2,000 fur coat instead of a \$5,000 fur coat, avoids an expense of \$3,000. She thus allegedly secures the equivalent of a \$3,000 raise for her husband. And if the husband could elevate his wife’s tastes sufficiently, to the point where she would set her heart on a \$15,000 fur coat, her expenditure of \$2,000 would allegedly secure for him the equivalent of a \$13,000 raise—enough to pay both for the coat for her and for a small sports car for him besides.

At the base of all these absurdities is the failure to realize the importance of earning *money* as the means of living in a division-of-labor society. As a result of this failure, contemporary economics does not consider the earning or nonearning of money to be a significant matter. As a further result, it does not know how to distinguish between production and consumption. It regards consumption as though it were production, merely because the physical aspect of production is present—failing to see that such production is a consumptive production.

In addition, contemporary economics considers as one of its main tasks the *measurement* of total production

and total welfare in the economic system, and believes that such measurement can be performed by adding up the number of dollars for which goods and services exchange or might be exchanged. The notion that the expenditure or potential expenditure of money in an economic system, is a measure of the goods and services which are produced in that economic system is totally mistaken. What the aggregate expenditure of money in an economic system reflects, and thus indirectly measures, is nothing but *the quantity of money* in the economic system!

As we shall see when we come to the discussion of the quantity theory of money in the next chapter, it is the quantity of money, not the volume of physical production, that determines the volume of spending in the economic system. Essentially, increases in the production of goods and services are accompanied by a rise in the total spending for goods and services only insofar as they are accompanied by an increase in the quantity of money. Otherwise, the increase in production results in a fall in prices, with basically no greater total expenditure of money taking place.

Money is important *within the economic system*, as the means of individuals exchanging their goods and services and as the basis of their performing economic calculations. It has no significance as a measure of the production of the economic system as a whole. Contemporary economics fails to see the real significance of money—in the activities of individuals—and focuses instead on the illusory significance of money as a measure of aggregate production.

This is not to say that a system of aggregate economic accounting is of no value. As will be shown later in this book, it is of very great value, but as a means of improving understanding of the functioning of the economic system, not as a system of measuring the production of the economic system.

6. Critique of the Opportunity-Cost Doctrine

An opportunity cost is an imputed cost—a cost which does not actually exist in the sense of an expenditure of money being made, or having been made, but which is treated as though it existed. An opportunity cost is said to exist by virtue of the failure to earn a revenue or income that otherwise might be earned or might have been earned. It represents the absence of a revenue or income, just as imputed income represents the absence of a cost.

The treatment of the subject by Samuelson and Nordhaus is typical:

... the economist generally includes more items in cost than do accountants or businesspeople. Economists include

all costs—whether they reflect monetary transactions or not; business accounts generally exclude nonmonetary transactions.

We have already encountered . . . examples of true economic costs that do not show up in business accounts. The return to an owner's effort, the normal return on contributed capital to a firm, a risk premium on highly leveraged owner's equity—these are all elements that should figure into a broadly conceived set of economic costs but do not enter business accounts. . . .

The notion that can help us understand this distinction between money costs and true economic costs is the concept of *opportunity cost*. The opportunity cost of a decision consists of the things that are given up by taking that particular decision rather than taking an alternative decision.³⁰

The opportunity cost of a decision is subsequently described as "the value of the best available alternative."³¹ Practically every elementary textbook of economics, including Samuelson and Nordhaus, offers an example of the following kind to illustrate the concept of opportunity cost and explain the need for it.

An accountant informs the owner of a neighborhood hardware store that he has made a profit of \$50,000 during the preceding year. Naturally, the owner may be quite pleased with having made such a profit. But this, interjects the textbook author, shows how little this businessman and his accountant know of economics. Have they considered, he asks, that by selling the hardware store and investing the proceeds elsewhere, the store owner could make \$15,000 per year in interest, and, by going to work for someone else, make \$45,000 in wages or salary? These forgone opportunities or passed-up alternatives, the textbook author then argues, must be counted as costs of the owner's business, just as much as the store's payment for merchandise and the labor of hired help, if its actual profit is to be computed. And thus, the textbook author concludes, far from having the \$50,000 profit that the store owner and his accountant naïvely believed he had, the store owner has incurred a \$10,000 *loss*. In the words of Samuelson and Nordhaus, in reference to their particular variant of this example: "Thus, while the accountant might conclude that such a typical small business was an economically viable enterprise, the economist would pronounce the firm an unprofitable loser."³²

Now the need for the concept of opportunity cost is simply supposed to be to make the store owner aware of the fact that he might be financially better off by selling out and going to work for someone else. But if this is so, there is no reason why it cannot be stated very simply that one can be financially better off making a larger income in the form of interest and wages than a smaller income in the form of profit. One is better off making a

combined \$60,000-interest-and-wage income than a \$50,000-profit income. In order to make this point, there is no need to deny that the store owner's profit is a profit, and to call it a loss instead. And there is no reason for the store owner to think he has done badly merely because he might have done better. There is certainly no grounds, as Samuelson and Nordhaus believe, to challenge the accountant's judgment that the enterprise is viable. It is indeed viable. It recovers in sales all the outlays it expended to bring in those sales, and a profit besides. Thus it is self-sustaining and more than self-sustaining. It is not a "loser"—not of a single dollar of the capital with which it began the year's operations.

The doctrine of opportunity cost is not required for ascertaining how one might do better. Its sole contribution is obfuscation, not perception. Consider its implications.

Our store owner, if we are to believe such authors as Samuelson and Nordhaus, has lost \$10,000. Nevertheless, he has gone through the year consuming \$40,000 and adding \$10,000 to his net worth. He has bought a car and taken a vacation, and, at the same time, added \$10,000 to his bank account. If he in fact had had a loss of \$10,000, this would not have been possible. Consuming \$40,000, while losing \$10,000, would have meant a decline in his net worth of \$50,000. How can this discrepancy of \$60,000 between the facts and the implications of the opportunity-cost doctrine be reconciled? How can the \$10,000 increase in the store owner's net worth, which in fact occurs, be reconciled with the \$50,000 decrease in his net worth which the opportunity-cost doctrine implies?

The solution to this puzzle is a second step into unreality, a second fiction to balance the first. It is that in addition to incurring the loss he never incurred, the store owner is alleged to receive income he never received! For not only does he have a \$10,000 loss, it is claimed, but he also earns \$15,000 in interest and \$45,000 in wages. His \$50,000-profit income is, it is claimed, in reality[!] a \$10,000 loss accompanied by \$60,000 in interest and wage income! And thus, paradoxically, the very interest and wage incomes which were *not* earned, and the failure of which to earn supposedly gave rise to the need for counting them as costs, are treated as being earned! They are held to be simultaneously not earned and earned.

What is involved in this juggling must be spelled out more fully. The store owner forgoes \$60,000 in interest and wage income by virtue of remaining in his present business. This \$60,000 which he does not make is treated as an outlay of his business, despite the fact that no such outlay exists. This nonexistent outlay then causes a nonexistent loss. The nonexistent loss, however, contradicts the change in the store owner's net worth. To reconcile

this contradiction, the store owner is then credited with a nonexistent interest and wage income equal to his nonexistent payment of interest and wages. He allegedly now earns the interest and wage income he doesn't earn and which, in not being earned, created the whole alleged problem in the first place. He supposedly pays the interest and wages he doesn't pay, to himself, so he now receives from himself the interest and wages he doesn't receive.

An analogy to this procedure would be the following. One gains ten pounds, but might have gained twenty pounds. This is then taken to mean that one has lost ten pounds. When one's alleged loss of weight cannot be reconciled with the fact that one is now ten pounds too large for one's clothes, one's oversize is explained on the grounds that one's clothes have shrunk the equivalent of twenty pounds. Or: one marries a pretty woman, but might have married a very beautiful woman. This is then taken to mean that one has married an ugly woman. When the woman's alleged ugliness cannot be reconciled with the fact that she is pretty, her prettiness is then explained on the grounds that she has had plastic surgery.

The opportunity-cost doctrine leads to further absurd implications. It follows from this doctrine that it can be more advantageous to have losses than profits. Our store owner allegedly suffers a \$10,000 loss because he forgoes \$60,000 in interest and wage income in making his \$50,000 profit. But suppose that instead of being the owner of a hardware store, he were only a poor pushcart vendor or street-corner newspaper dealer. His profit in such a case might be only \$20,000. Yet if the interest he had to forgo on his tiny capital and the wages he had to forgo on his very limited talents amounted to only \$15,000, the opportunity-cost doctrine would claim he had made a profit of \$5,000. Obviously, it is much better to suffer the \$10,000 "loss" than to make this \$5,000 "profit."

It follows from the opportunity-cost doctrine that precisely to the degree that one is confronted with profitable ways to invest one's capital, and precisely to the degree that one's services are in great demand, one's income must be less—in a word, that one must suffer by virtue of possessing the very qualities that create one's success. For example, it follows from this doctrine that companies reduce their profits by having successful research departments. The effect of these research departments is to create profitable alternative opportunities for investment. According to the opportunity-cost doctrine, to the degree that they do this, they must raise the costs of these firms and thus reduce their profits. For example, if an innovative computer company or pharmaceutical company is able to make a rate of profit of 30 percent on some product, that profit must allegedly be reduced to 1 percent if its research department develops some other

product which could afford a 29 percent rate of profit on the same capital. And if the new product could yield 31 percent, then the company's rate of profit must allegedly still be cut to 1 percent, because then the profit on the original product would constitute the opportunity cost. And if the company's research department develops two truly spectacular products, the one yielding a 50 percent rate of profit, the other a 49 percent rate of profit, again its rate of profit must allegedly be cut from 30 percent to 1 percent on the capital in question. Conclusion? The first step for a company to take if it wants to raise its rate of profit is to close down its research department.

Similarly, it follows that the president of General Motors must suffer from the fact that Ford and Chrysler would like to employ him, for to the degree that they become aware of his talents, it serves to raise his opportunity costs. He would allegedly make a higher income if no other auto firm were interested in him. Conclusion? Raise your income by striving to give the impression to potential employers that you are incompetent. If you can succeed in this endeavor sufficiently, you will make more money, the opportunity-cost doctrine implies, even if your "mere" accounting income falls, provided it doesn't fall by as much. And, of course, the best and quickest way to raise one's income is simply to make oneself blind to all alternative possibilities for investment and employment, and thus to remove them as opportunities, thereby totally eliminating all "opportunity costs."

Yet another manifestation of the absurdity of this doctrine can be seen if it is applied to the stock market. Imagine that an individual is considering investing a million dollars, and must decide between two stocks, *A* and *B*. Both stocks are currently selling at \$10 per share. The individual decides on stock *A*. It goes to \$20 per share. In the same period, however, it turns out that stock *B* goes to \$30 per share. If one believes the opportunity-cost doctrine, this is grounds for leaping from the nearest skyscraper—one has lost a million dollars. Conversely, imagine that stock *A* drops to \$3 per share, while stock *B* drops to \$1 per share. In this case, if one believes the opportunity-cost doctrine, one has made \$200,000 and can afford to buy a Rolls Royce.

The criticisms I have made of the opportunity-cost doctrine should by no means be interpreted to mean that I deny the relationship between the cost of producing an individual good and the value of the alternative products which can be produced with the same factors of production. On the contrary, I fully acknowledge that costs of production are influenced by the value of alternative products which must be forgone if the product in question is to be produced. Indeed, previous portions of this book were devoted actually to demonstrating just how

this process takes place.³³ For example, insofar as it depends on the price of wheat, the cost of producing bread is determined on the basis of the value buyers attach to other wheat products, such as meat produced from animals fed with wheat—products which cannot be produced because the means of producing them are devoted to the production of bread and are thus unavailable to produce those alternative products.³⁴

But these costs of production are *money costs* of production. The actual *money price* of wheat (and of all other factors of production that exist in a given supply) is determined by a process of bidding that emanates from all the different uses and users of the factor of production. The price of the factor emerges as the result of the bidding of different *sums of money* by the various users and potential users. This process does not at all represent the concoction of any kind of make-believe costs. The costs are actual, in the full business and accounting sense.

The supporters of the opportunity-cost doctrine generally recognize the process by which money costs are determined, then confuse the alternative opportunities whose competition in bidding gives rise to the money costs with the phenomenon of cost itself, and thereafter ignore the necessity of a money outlay actually being present. In other words, they identify a cause of the determination of money costs, confuse the cause with the effect, and proceed to ignore the effect, which is nonetheless essential.

The first part of this chapter was dedicated to dealing with those errors in connection with the concept of productive activity that define it too broadly, by failing to take into account the vital importance of moneymaking. The second part of this chapter, of course, will deal with the deadly errors of defining the concept of productive activity too narrowly and excluding from it such vital activities as those of businessman and capitalist, retailer and wholesaler, and so forth.

The imputed-income and opportunity-cost doctrines constitute a kind of bridge between the two types of errors. In leading people to perceive the existence of productive expenditures, wages, and costs where there are in fact no productive expenditures, wages, or costs, and to deny the existence of profits where profits do in fact exist, they encourage an utter misconception of the foundations and mutual interrelationships of these phenomena. In particular, they blot out the essential role of businessmen and capitalists in the making of productive expenditures and the payment of wages, and proceed as though productive expenditure and wages could exist without businessmen and capitalists. In so doing, they thoroughly distort the nature of the activities of businessmen and capitalists and the relationship between those

activities and the respective heights of wages and profits. Thus, they play a major role in preventing a just conception of the productive role of businessmen and capitalists and in making the Marxian exploitation theory appear plausible. This will become clear in what follows.

PART B

THE PRODUCTIVE ROLE OF BUSINESSMEN AND CAPITALISTS

1. The Productive Functions of Businessmen and Capitalists

As previously observed, the productive role of businessmen and capitalists can be understood only within the context of a division-of-labor society. While in a non-division-of-labor society, manual workers alone are productive, because there is nothing more to production in such a context than the physical making of goods, in a division-of-labor society new aspects, new dimensions, of productive activity appear. Money-making is only one such aspect, though an essential one, to be sure. In addition, the productive role of businessmen and capitalists emerges. Their productive role is to raise the productivity of manual labor, and thus its real remuneration, precisely by means of *creating, coordinating, and improving the efficiency of the division of labor*.³⁵

Businessmen and capitalists create division of labor in founding and organizing business enterprises, in providing capital, and in making productive expenditures. They coordinate the division of labor among the various firms and industries by the very fact of seeking to make profits and avoid losses; they coordinate the division of labor within each individual firm insofar as they perform the functions of management. They improve the efficiency of the division of labor both by means of their competitive quest to earn the highest possible rate of profit, and to avoid losses, and by means of providing capital and seeking to maximize the efficiency with which capital goods, no less than labor, are employed.

Each of these aspects of the productive role of businessmen and capitalists requires elaboration.

Creation of Division of Labor

Business firms are the central units of a division-of-labor society. The division of labor exists both between the various individual business enterprises and within each individual business enterprise that comprises the labor of more than one person. Each business firm is more or less specialized in its production. Frequently, its activities are confined to a single industry; rarely do they

extend to more than several industries. The cases in which firms do participate in more than a few industries will generally be found to be the result of artificial incentives created by the tax laws.³⁶ In absolutely no case, does any firm come even remotely close to engaging in all branches of production. Thus, each firm represents more or less specialized productive activity vis-à-vis the rest of the economic system. Furthermore, within each firm, there are separate divisions, departments, sections, and branches, all representing further aspects of the division of labor.

In these ways, business firms are the central units of a division-of-labor society, representing division of labor both in their external relationships to other business firms and in their internal organization.

It follows that in founding and organizing business firms, businessmen and capitalists create division of labor—they construct the building blocks of the division-of-labor society.

The provision of capital by businessmen and capitalists is no less essential to the existence of the division of labor. As explained in the discussion of the dependence of the division of labor on saving, the provision of capital is indispensable to the existence of any significant vertical division of labor. This is because it makes possible the existence of a necessary division of payments in the productive process. In its absence, the only source of payments to producers would be the ultimate consumers, with the result that many groups of producers would be compelled to wait intolerable lengths of time between the completion of their contribution to production and their receipt of payment. This is the problem of the auto workers and steel firms having to wait to be paid until the cars they help to produce are sold, or, if the cars are sold on credit, as they often must be, until the installment payments come in. It is the problem of the steel workers and the iron-mining concerns having to wait all this length of time plus the additional length of time that elapses between their contribution to production and the payment for the automobiles, and so on, with the problem growing worse and worse, the further back in the chain of production one stands. It is the problem of the equipment and construction industries and their workers having to wait decades for payment, and even generations and centuries, insofar as equipment and buildings are used in the production of further equipment and buildings.³⁷

In contrast, the provision of capital makes possible payment to producers at numerous points in the productive process, and thus within a reasonable period of time following the performance of their contribution to production. Indeed, in a modern economic system the great majority of wage earners are paid out of the capital of the firms which employ them. This makes it possible for

them to be paid in most cases not only far in advance of payment by the ultimate consumers, but also even well before the business firms at the next stage of production pay for the products to which their labor contributes. For example, steel workers are paid not only years in advance of the payment for automobiles by the ultimate consumers but also well in advance of the payment for steel by the auto companies. Wages are paid out of the capital of the firm that employs the wage earners in every instance in which payment must be made to the wage earners after a shorter interval of time than that in which payment is received by the firm for the goods or services to which their labor contributes. This, of course, occurs in the typical case in which wages are paid after a week's work and payment from the customer for the goods or services to which the wage earner's labor contributes is payable to the firm as late as thirty days later, without penalty.

There is a closely related point of great importance. Namely, later portions of this book—of this chapter—will show how the saving and productive expenditure of businessmen and capitalists are responsible for the existence of the entire demand for labor in the production of products for sale—both for first creating that demand and then increasing it relative to the demand for consumers' goods.³⁸ It will be shown that to the degree that businessmen and capitalists save and productively expend, they increase the proportion of "national income" that is constituted by wages and the proportion of consumption expenditure that takes place out of wages in contrast to other forms of income, notably, profits and interest. Indeed, it will be shown later in this chapter that it is the saving and productive expenditure of businessmen and capitalists that make possible the very existence of a class of wage earners separate and distinct from the sellers of products, and thus of the existence of the division of labor insofar as it depends on the existence of wage earners.³⁹

It should not be forgotten that the provision of capital also vitally contributes to the division of labor in its horizontal aspect—that is, the extent to which it can be carried at any given stage of production. This is because greater division of labor at any given stage of production requires the existence of larger-scale production, which in turn requires the existence of greater amounts of capital.⁴⁰

Thus, in founding and organizing business enterprises, in providing capital, and in making productive expenditures, businessmen and capitalists create division of labor.

Coordination of the Division of Labor

Businessmen and capitalists are responsible for the coordination of the division of labor among the various branches of production by virtue of their striving to make profits and avoid losses. As the discussion of the price system showed earlier in this book, in striving—other

things being equal—to make the highest possible rate of profit, businessmen and capitalists are led to counteract the mistake of relative underinvestment and relative underproduction. This is the mistake of failing to carry investment and production in specific industries far enough relative to investment and production in the rest of the economic system. For example, the mistake of failing to carry investment and production in the automobile industry far enough relative to investment and production in the housing industry, or investment and production in the manufacture of nails far enough relative to investment and production in the lumber industry. By the same token, in seeking to withdraw their capital from industries suffering losses or earning below-average rates of profit, businessmen and capitalists are led to counteract the mistake of relative overinvestment and relative overproduction—that is, the mistake of carrying some branches of production too far relative to the other branches of production. To be sure, the desire to make profits and avoid losses leads businessmen and capitalists to strive to avoid making mistakes representing either kind of discoordination in the first place.

In these ways, the profit motive of the businessmen and capitalists operates as the great engine maintaining coordination and balance among all the different branches of the division of labor. It is what prevents the division of labor from degenerating into any sort of "anarchy of production."⁴¹

The coordinating function of businessmen and capitalists is present not only among the different branches of production, and the various individual firms which comprise them, but also within each individual firm. Insofar as businessmen and capitalists exercise the functions of management, which to some extent they do inescapably in deciding the activities and organization of their enterprises, they are engaged in a further process of coordinating the division of labor. It is the essence of management to direct the activities of subordinates—individuals and groups of individuals comprising subordinate units—in such a way as to achieve the cohesive, overall goals of the enterprise at large. This is precisely the coordination of the elements of division of labor within the enterprise.

Of course, as I explained in Chapter 9, as far as the economic system is free of government interference, the managerial activities of the businessmen and capitalists represent profit management as opposed to bureaucratic management. The latter is the nature of management in government enterprises. It appears in private enterprises only to the extent that they are subject to government interference.⁴²

By now one should be able clearly to appreciate just

why comprehension of the division of labor is the key to understanding the productive activities of businessmen and capitalists. If one ignores the division of labor, and focuses instead on the conditions of production in a society of self-sufficient farmers or hunters, there is no specific productive activity for businessmen and capitalists to perform. There is no division of labor to coordinate and no division of labor to create in the first place, and thus there is no possibility of grasping that precisely these are the productive functions of businessmen and capitalists. Nor, of course, on such a view is it possible to grasp the vital productive role of businessmen and capitalists in improving the efficiency of the division of labor.

Improvements in the Efficiency of the Division of Labor

The discussion of the price system earlier in this book, in particular that of the uniformity-of-profit principle, also makes very clear how the profit motive of businessmen and capitalists brings about a progressive improvement in the methods of production and in the quantity and quality of the products produced.⁴³ We saw major confirmation of this principle in the discussion of the nature of economic inequality in a capitalist society, in particular in connection with the building of great industrial fortunes.⁴⁴

It is only necessary to recall the fact that under the freedom of competition of capitalism, to earn an exceptional rate of profit a producer must introduce a better product or a more efficient method of producing an already existing product. And, further, that the effect of the freedom of competition is subsequently to erode any special profit made in this way, as the improvement becomes more and more widely adopted by others and becomes the normal standard of the industry, with the result that to go on earning an exceptional rate of profit, it is necessary to introduce *repeated improvements* in production.

Later discussion of saving and capital accumulation in Chapter 14 of this book will show how the saving and productive expenditure of businessmen and capitalists result in a growing supply of capital goods and thus in the achievement of a further indispensable precondition for a rising productivity of labor. That discussion will also show how the efficiency that the profit motive leads businessmen and capitalists to achieve in the utilization of the capital goods already existing at any given time further powerfully promotes capital accumulation and the rise in the productivity of labor.⁴⁵

Thus, in these ways—namely, the introduction of continuous improvements in products and methods of production and the achievement of capital accumulation both through saving and productive expenditure and the

efficient use of already existing capital goods—the activities of businessmen and capitalists bring about a progressive improvement in the efficiency of production under the division of labor.

2. The Productive Role of Financial Markets and Financial Institutions

The fact that in a division-of-labor society, production begins with an outlay of capital, and is thoroughly dependent upon the availability of capital, underlies the productive role of financial markets and financial institutions—namely, of the stock and bond markets, the banking system, and financial markets and financial institutions in general. The essential productive role of these markets and institutions is to promote the investment of savings and the efficiency of the investment of savings, as well as the overall degree of saving, and thereby to raise the demand for and productivity of labor and the general standard of living. Essentially, it is similar to the productive role of businessmen and capitalists themselves insofar as they provide capital and are responsible for a growing supply of capital goods.

The existence of financial markets and financial institutions makes it possible for individuals to earn a rate of return on capital without having to employ that capital in businesses of their own. It makes it possible for them to invest in businesses owned and operated by others, and to earn a rate of return on capital in the form of interest and dividends rather than in the form exclusively of profit. For many people, the existence of these markets and institutions provides the only opportunity of earning a rate of return on their savings.

In the absence of financial markets and financial institutions—of lending and borrowing and of investing for dividends—the only way that individuals could earn a rate of return on their savings would be by investing them in businesses under their own management. The possibility of investing in the enterprises of friends or close associates in the form of lending or accepting a partnership in which one plays no role in the management already represents the existence of a primitive, highly circumscribed form of financial market. Such limited possibilities may be of significant value to those to whom they are open, but they are obviously of substantially less value than the existence of full-fledged financial markets and the vastly greater opportunities for investment that the latter afford. Moreover, they are of no value for the great majority of individuals, whose friends and close associates are unable to offer the prospect of worthwhile investments.

Thus, in the absence of financial markets and financial institutions, for the great majority of people, if not for

everyone, the only means of earning a rate of return on their savings would be investment in businesses under their own management. Yet there are many individuals for whom it would be highly disadvantageous to have to run a business of their own, given the alternative of being employed for wages that are higher than the profits they could hope to make in business for themselves. This in fact is the case for the great majority of people today, who can work as employees in fairly well-paying positions, but who, if they had to live by being in business for themselves would earn much less, or even lose the capital they invested.

Then, of course, there are many other people who possess savings, but who are completely unqualified to run a business, such as almost all underage orphans and many widows. In addition, there are still other people who possess savings and who might be financially more successful in business than in their present occupations, but who are simply unwilling to devote the necessary time to business activity. In this category are probably a significant number of professionals, such as doctors, lawyers, engineers, and professors.

Still another, partly overlapping group is constituted by all those people who possess savings and have successful businesses of their own, but who cannot employ all of their savings efficiently within the limits of their own businesses. In this category are many professionals in private practice, large numbers of small businessmen, and a significant number of large businessmen. For example, a doctor in private practice often easily accumulates far more savings than he can employ efficiently in his practice. The owners of many successful stores and shops are in the same position. If such people are unable or unwilling to open branches or enter into additional lines of business, or cannot do so efficiently, then they simply cannot employ all of their savings, or, at least, cannot employ them efficiently.

On the basis of these facts, it should be obvious that the absence of financial markets and financial institutions would mean that to an important extent individuals who had savings would have no incentive to invest them. Individuals in such a position would thus have no alternative but to hold their savings in the form of hoards of money or accumulations of consumers' goods, such as jewelry, housing, and works of art. The consequence would be that their savings would not serve to make possible a demand for capital goods or for labor. The result of the lesser demand for capital goods would be that the extent to which the economic system concentrated on the production of capital goods would be correspondingly less. And thus the ability to achieve a production of capital goods sufficient to make possible capital accumulation would be correspondingly less. The

effect would almost certainly be economic stagnation at an extremely low level of productivity of labor. The standard of living of the average worker would also suffer from the fact that savings that are hoarded or held in the form of accumulations of personal consumers' goods do not contribute to the demand for labor and the payment of wages, as do savings that are invested.

In contrast, the existence of financial markets and financial institutions, and the rate of return they provide, greatly encourages the investment of all such savings. The fact that financial markets and financial institutions exist thus raises the relative demand for and production of capital goods and thereby powerfully contributes to capital accumulation and a rising productivity of labor. At the same time, it raises the relative demand for labor and payment of wages.⁴⁶

In addition, and also very important, the existence of financial markets and financial institutions enables individuals who have the opportunity of investing in their own businesses, to invest more productively in businesses owned by others. This, too, powerfully contributes to capital accumulation and the rise in the productivity of labor and the general standard of living. It does so, above all, by making possible the existence of the large aggregations of capital necessary for such undertakings as electric utilities, railroads, and, indeed, most large-scale modern industries. In this way, the surplus capital accumulated by such people as doctors and shopkeepers can be employed far more effectively than in further enhancements of such things as office furniture or perhaps a store's inventory.

The effect of this change in the pattern of investment made possible by the existence of financial markets and financial institutions is that with the same degree of demand for capital goods and concentration on the production of capital goods, the economic system is able to produce far more. This is because now it has capital goods in the form of electric power plants and the like, rather than in the form of such things as minimally useful additional office furniture. The effect of the greater ability to produce that this change in the pattern of investment makes possible is a larger supply not only of consumers' goods, but also of *capital goods*. For the existence of electric power plants, railroads, steel mills, and so forth contributes as much to the production of a larger supply of capital goods as it does to the production of a larger supply of consumers' goods. Thus, in this way too—by bringing about a higher productivity of capital goods—the existence of financial markets and financial institutions powerfully contributes to capital accumulation and the rise in the standard of living. And, as we shall see in later discussion of capital accumulation, the effect of a higher productivity of capital goods is a continuing

one, making possible a permanently higher rate of capital accumulation.⁴⁷

To an important extent the existence of financial markets and financial institutions encourages not only the investment or more efficient investment of savings already made but also an increase in the rate of saving itself. In enabling individuals who otherwise could not have earned a rate of return on their savings now to earn one, or to earn a higher rate of return than they otherwise could have, it increases the overall rate of saving.

It is important to realize that this does not occur to any great extent by increasing the incentive to save. Most people would desire to have savings even in the absence of any rate of return—simply as a means of providing for future needs that they could not expect to provide for otherwise. And to the extent that people already have savings for such reasons, the effect of the ability to earn a rate of return, or a higher rate of return instead of a lower rate of return, may be as much to motivate them to consume more in the present as it is to give them an incentive to save more in the present. This is because counterbalancing the fact that each dollar saved today will now turn into more dollars in the future is the prospect of the higher future income that will be available as the result of the higher rate of return on the savings one already has. The prospect that one will be better off in the future than in the present operates as an inducement to consume more and save less in the present. Thus, the overall effect of being able to earn a rate of return, or a higher rate of return, on the incentive to save may well be neutral or close to neutral.

Nevertheless, the ability to earn a rate of return does powerfully promote saving. It does so insofar as it enables individuals whose consumption would otherwise be at the expense of their accumulated savings to consume without decumulating their savings. For example, the fact that an individual with accumulated savings of, say, one million dollars can earn a rate of return (in real terms) of 2 or 3 percent a year enables this individual to consume twenty or thirty thousand dollars a year without depleting his savings.

In the absence of his ability to earn a rate of return, the greater part of the savings accumulated by an individual would later on be decumulated, as they came to be used for current consumption. Instead, the ability to earn a rate of return serves to enable an individual with accumulated savings to consume out of income rather than his accumulated savings.⁴⁸ In so doing, it makes possible a far higher overall rate of saving and correspondingly greater degree of capital accumulation and demand for labor.

Once again, it must be emphasized how the produc-

tive role of such a segment of the economic system as financial markets and financial institutions can be understood only within the context of a division-of-labor society, and only after one has understood the role of capital in production in such a society. It is absolutely impossible to understand it, if one's context is essentially limited to that of Robinson Crusoe producing on a desert island and standing outside the division of labor and the use of money. In that case, one simply cannot appreciate the fact that in a division-of-labor economy production must begin with outlays of money, and that the productivity of labor depends both on the relative production of capital goods and on their productivity, both of which are greatly increased by the existence of financial markets and financial institutions and the greater saving, investment out of saving, and more efficient investment that they make possible.

The Specific Productive Role of the Stock Market

A widespread misconception is that the stock market is somehow divorced from genuine productive activity except insofar as it is the source of funds going directly to corporations in exchange for newly issued stock. On this view, the overwhelming bulk of stock market activity, which consists of the trading of already outstanding shares, makes little or no contribution to the productive process.

It should be realized that the ability of stockholders to sell their shares provides a major inducement to the purchase of those shares in the first place. If it were not for the existence of the stock market and its continuous trading in already issued stock, any purchaser of newly issued stock would be faced with the prospect of not being able to sell his stock, or of being able to do so only with great difficulty. Such a prospect would greatly discourage the initial purchase of stock from the issuing corporations and would thus greatly reduce the availability of capital to those corporations. The existence of the stock market and its continuous trading in outstanding shares makes it possible for the individual investor to liquidate his investment at virtually any time, even though the funds initially supplied to the corporation itself may be invested in assets that have a productive life of several decades or more and cannot be recovered from business operations in any less time than that, and, indeed, will most likely be permanently retained by the business enterprise in which they have been invested.

Furthermore, it should be realized that the sale of already issued stock can be, and very often is, the source of funds for investment in the actual physical assets of a business by the individual shareholders who sell their holdings. For example, the owner of a drug store or restaurant who owns stock in IBM or General Motors,

say, may very well decide to sell his shares, or use them as collateral on a loan, in order to raise money to expand his own business activities. In this way, the stock market provides a source of funds for investment in physical assets of business through the trading in already outstanding shares.

The determination of the price of stock in the market for already outstanding shares plays a major role in deciding whether or not it is worthwhile for the present stockholders to have their corporation issue additional shares. Other things being equal, the higher is the price of a share of its stock, the smaller is the percentage of the corporation that must be given up in order to raise any given sum of money, and thus the more likely is it that it will be worthwhile for the present stockholders to have the corporation sell additional stock. By the same token, the lower is the price of its stock, the less likely is it to be worthwhile for the present stockholders to have their corporation sell additional shares. For example, if a corporation has 1 million shares of stock outstanding, and the price of its stock is \$10 per share, then in order to raise a million dollars through the sale of new stock, it must sell an interest to outsiders that will amount to one-eleventh of itself—i.e., 100,000 shares out of a new total outstanding of 1.1 million shares. If the price of the corporation's stock were \$100 per share, however, then it could raise an additional million dollars by selling to outsiders less than 1 percent of itself—i.e., only 10,000 shares out of a new total of 1 million shares plus 10,000 shares. By the same token, if its stock had a market value of only \$1 per share, it would have to sell 50 percent of itself in order to raise a million dollars. On this basis, it should be obvious that the stock market plays a decisive role in determining whether or not a corporation will find it worthwhile to issue new stock.

In connection with this point, it must be said that the stock market makes it possible for firms that demonstrate their success to obtain capital at a much faster rate than they could if they had to rely exclusively on the reinvestment of their profits. A firm's demonstration of the ability to earn a high rate of profit on its existing capital operates to raise the price of its outstanding shares and thus to make it possible and worthwhile for the firm to obtain substantial additional capital from the sale of additional stock. In this way, the firm can obtain control over larger sums of capital more rapidly than would otherwise be the case. Indeed, if it increases its equity in this way, the firm correspondingly increases its capacity to borrow and can thereby raise still more capital if it wishes. By these means, successful small businesses are enabled to grow into large businesses and play a more important role in the economic system more rapidly than they otherwise could. At the same time, as an important consequence,

they are enabled to challenge the existing large firms all the more rapidly.

Finally, it must be pointed out that the existence of the stock market serves to penalize poor management and to offer a protection against the abuse of stockholders by corporate managements. The effect of poor management, or of the abuse of stockholders, is a low price of the firm's stock relative to the value of the firm's assets. This situation invites an outside takeover of the firm, the firing of its present management, and, very often, the sale of some or all of its assets to other firms which are capable of putting them to better use. Apart from anything else, the mere fact of changing circumstances, and the inability of many corporate managements to keep pace with the changes, repeatedly necessitates the breakup of existing corporations, as the land sites their facilities occupy and often the facilities themselves and much of their equipment become more useful in other employments than in their present employments.

Regrettably, in the present-day United States, this important function of the stock market, of serving to bring about the redeployment of the physical assets of business firms in different hands and often for different purposes, is threatened by government intervention designed to protect incompetent managements from the threat of outside takeovers. With the narrow-minded perspective that is typical of opponents of the free market, the enemies of corporate takeovers can see only that some existing "jobs" are eliminated. They do not see the new employment opportunities that are created in other firms, accompanying the availability of the capital assets that have been sold to them. They are unaware that the very fact that the assets of a firm are worth more in being sold off than in being retained is virtual proof that their employment elsewhere will be more productive and thus will contribute to a more rapid rate of capital accumulation and a higher productivity of labor. They do not even see that corporate takeovers, followed by the selling off of assets, are a powerful remedy for previous ill-conceived mergers, whose existence, along with all other mergers, the enemies of capitalism never tire of denouncing.

3. The Productive Role of Retailing and Wholesaling

The productive contribution of retailing and wholesaling becomes apparent as soon as one realizes that in a division-of-labor society, the supply of every product originates in a great concentration, in the hands of a relatively small number of producers. In order for any benefit to be derived from these supplies, they must be moved into the hands of the vast body of consumers which, from the perspective of any one branch of production, is constituted by the producers and their depen-

dents in all the other branches of production. Retailing and wholesaling, along with exchange and money, are the means whereby goods are moved in this way.⁴⁹ Thus, the existence of retailing and wholesaling is essential to the solution of a problem that exists only in a division-of-labor society, in which the producers of any given item are different individuals than the overwhelming majority of its consumers.

The failure to appreciate the value of retailing and wholesaling rests on the failure to keep in mind the existence of the division of labor and then to approach the subject of production and consumption as though all that were required to consume was physically to produce. In such a view of the economic world, dominated by the image of conditions in a pre-division-of-labor society, it appears that retailing and wholesaling are useless appendages to what really counts: i.e., the mere physical production of goods. On such a view, what is accomplished by retailing and wholesaling appears to be nothing but the addition of “markups” by useless “middlemen” to the prices charged by manufacturers and farmers, which prices are all that the consumers justly ought to be made to pay.

In the reality of a division-of-labor society, however, retailing and wholesaling play an essential role in the benefit derived from physical production. They are responsible for a major reduction in the amount of time and money that would otherwise need to be spent in obtaining goods, and for an equally major increase in the variety and quality of goods available.

In the absence of retailing and wholesaling, either the consumers would have to go to the producers or the producers would have to come to the consumers. The difficulty of the consumers going to the producers is evident if one simply imagines what it would be like to assemble the ingredients of an ordinary breakfast. A person would have to drive out to the countryside to buy bacon, eggs, and milk. And, if he wanted choice among his suppliers, he would have to drive to more than one farm for each item. In all probability the cost just of fuel and wear and tear on his automobile would be far greater than any “markups” added by retailers and wholesalers. In addition, we must consider the fact that all the time he had to spend in such activities would mean that he would have that much less time available either for earning a living or for leisure.

These points would apply even if individual consumers got together and formed groups for the purpose of purchasing supplies. For example, one might imagine a group of neighbors or fellow employees getting together to send representatives to the producers for the purpose of purchasing in bulk and coming back with supplies for all members of the group. They might agree that every

week one of their number would make a series of trips for all of them. They might pool their resources and buy a small truck to be used for this purpose. Perhaps the activity would become the full-time employment of one or two of them. But all of this sort of activity would simply represent consumers’ attempting to do for themselves what retailers and wholesalers can do for them with far greater efficiency.

Comparable difficulties would exist if the producers were to attempt to come to the consumers.

In the circumstances of an economy in which towns and cities are surrounded by large numbers of family farms that are relatively unspecialized, the local farmers can regularly bring a wide variety of farm products into the towns and cities and sell them in farmers’ markets. However, to the degree that an economic system is characterized by a higher degree of division of labor, this becomes unfeasible. For one thing, the degree of specialization of the various farms and agricultural districts increases, because of the greater efficiencies in production that such specialization achieves. Thus each agricultural district now tends to concentrate on the production of just one or a very few items. For example, one area concentrates on dairy farming, another on growing grain, a third on growing apples, a fourth on raising citrus fruits, and so on. At the same time, because of further efficiencies in production, there is the development of large-scale processing and manufacturing facilities. For example, most of the meat packing and flour milling in the United States now take place in a relatively small number of locations; canned goods, frozen foods, and a wide variety of baked goods, are also produced in plants in a relatively small number of locations. The same is true of clothing and furniture manufacture, automobile and appliance manufacture—of the production of most goods. These developments are incompatible with the existence of any wide range of nearby, local producers. Thus, it is more and more out of the question for the producers to come to the consumers. It would be one thing for a dairy farmer on Long Island to bring his butter and cheese into New York City. It is out of the question for a dairy farmer in Wisconsin to do so—or for a meat packer in Cincinnati or a biscuit manufacturer in Chicago to do so. Even more fantastic would be the prospect of a coffee grower in Brazil attempting to do so. (These difficulties, of course, would apply equally to consumers attempting to go to the producers.)

If products had to meet the requirement of being available directly from the producers, whether at the farm or the factory, or in local producers’ markets, the producers for the most part would have to be local, correspondingly small and less efficient, and perhaps altogether incapable of producing the product desired. A

possible exception would be cases such as automobiles, in which the items produced were of sufficient value to justify the manufacturer setting up his own specialized distribution network. (In actual practice, however, even in such cases the distribution network is almost always made up of independent retailers, who buy from the manufacturer rather than being part of the manufacturing firm itself. For example, automobile dealers are independent business firms, not part of the automobile companies themselves. This type of arrangement exists because the auto firms and other major manufacturers find it more efficient. They do so for such reasons as not having to invest as much capital of their own as would otherwise be required and because of the greater incentives ownership provides to the dealers.)

Another possible exception to the rule that the producers can no longer come to the consumers is the case of a manufacturer's mail-order business. Mail order in general, however, is a feasible method only in cases in which one does not need to physically examine the specific goods before buying them and can wait a more or less extended period of time for receipt of the goods (which last typically precludes perishable goods other than those sent by express, at a substantially higher cost). In the case of buying by mail order directly from a manufacturer, the additional requirement must be met that the customer is willing to go to the trouble of expending the time and effort to place the particular order, a circumstance which militates against buying any large number of inexpensive items from a host of separate manufacturers. The disproportionately high cost of advertising relatively inexpensive items that are offered singly or together with only a small number of other such items also militates against the use of mail order. Because of these facts, many mail-order businesses are retailers, which carry the merchandise of a large number of manufacturers. This enables the firms to advertise a large number of items at the same time, thereby saving on advertising costs and thus making it possible to charge lower prices for the products. At the same time, it enables the customer to order a variety of items at one time, thereby saving him substantial time and effort, not to mention expense.

Exactly the same advantages that are present in mail-order retailing are present in the more usual form of retailing through stores, plus, of course, the further advantages of being able physically to examine the goods one is buying and, as a rule, to take possession of them immediately. Retailing and wholesaling make it possible for producers to specialize in the production of an extremely narrow range of goods, such as just paper clips or just rubber bands, just spinach or just lettuce. Because of retailing and wholesaling, the producers of such isolated goods avoid the enormous wastes that would be

entailed in attempting to advertise and sell them one at a time to the consumers. They avoid such absurdities as having to place newspaper ads describing the availability and price just of paper clips or just of spinach, and of having to have a special sales representative and rent a special space to sell just this one item.

This discussion provides the appropriate basis on which to judge retailing and wholesaling. True enough, the costs of retailing and wholesaling and the profits of retailers and wholesalers must be added to the prices charged by manufacturers and farmers to arrive at the prices charged to the ultimate consumers. But, in the great majority of cases, the prices charged by manufacturers and farmers at their factories or farms are far from the total of what consumers would actually have to pay if the services of retailers and wholesalers were not present. In the great majority of cases, the consumers would then have to pay an addition to the prices charged by manufacturers and farmers at their production sites that would be far higher than the addition attributable to retailing and wholesaling. They would have to pay an addition that would cover the costs either of their inefficiently going to the producers or of the producers inefficiently coming to them. And, of course, in most cases, the prices charged by the producers even at their production sites would have to be substantially higher, because of the higher costs of production when markets must be local and small and the volume of production correspondingly limited; and, in still many other cases, the products would simply be completely unavailable. Thus, in comparison with the alternatives that would exist in the absence of retailing and wholesaling, it is obvious that retailing and wholesaling reduce the cost of goods to consumers, not increase them.

Retailing and wholesaling represent division of labor in the process of distribution. Instead of each group of consumers having to have a few volunteers or one or two hired hands, instead of each producer having to have his own distribution network—instead of the enormously wasteful duplication of labor and facilities that these things would entail—a relatively small number of retailers and wholesalers bring together in convenient locations to buyers the goods of an enormous variety of producers, and almost always at a far lower cost than would be possible for the consumers or producers acting on their own. A retail store frequently carries the products of dozens or even hundreds of different manufacturers or farmers, and usually of competing producers of the same product. Every such store means the saving of expense to consumers of not having to send their own purchasing agents, trucks, and so forth out to the dozens or hundreds of manufacturers or farmers whose products the retail store carries. It means the saving of expense to producers

of not having to send out their own salesmen and establish their own distribution outlets wherever they sought to sell their goods. Each retail store almost always buys in larger quantity, greater variety, and more efficiently than could any group of consumers. And it holds the products it buys in constant readiness to meet the demands of its customers at their convenience. At the same time, the existence of retail stores (and retail mail-order houses) makes it possible for producers to reach far more consumers than they could possibly do on their own, and to do so far more economically than they could do on their own. Thus, as I say, retailing and wholesaling reduce the cost and increase the variety of goods available to consumers, as well as make them available far more conveniently.

A few special words need to be said in connection with the economies achieved by the existence of wholesalers. The existence of wholesalers permits a radical reduction in the number of transactions that would otherwise have to exist between retailers and manufacturers. Imagine, for example, the existence of a thousand retailers in a given territory who each carry the products of a hundred different manufacturers—for example, small newsstands that sell cigarettes, candy, paperback books, magazines, and a variety of other such items. If each of these retailers had to deal with each of the manufacturers, there would be a hundred thousand different transactions. There would be a hundred thousand combinations of salesmen's visits, letters, phone calls, and so on. Each transaction would be for a relatively small amount of merchandise.

Now, in contrast, imagine the existence of a wholesaler, who stands between the retailers and manufacturers. In this case, there need be only a thousand large transactions between the retailers and the wholesaler, in which each retailer orders the goods of the hundred manufacturers all at the same time from the wholesaler's representative, and an additional hundred very large transactions between the wholesaler and the manufacturers, in which the wholesaler orders all at the same time merchandise from each manufacturer that is sufficient for all one thousand retailers. This means a total of only eleven hundred combinations of salesmen's visits, letters, phone calls, and so on, instead of a hundred thousand. And this, in turn, means a major reduction in transactions costs, and probably also in manufacturing costs, insofar as it permits manufacturers more easily to estimate the volume of production they need to prepare for. It also means that merchandise can be stored much more economically. The wholesaler can store merchandise in a warehouse, in a low-rent district, rather than each retailer having to store substantial amounts of merchandise on his premises, which are typically in a higher-

rent district, or in his own separate storage facility, which would entail further diseconomies of the kind associated with unnecessary duplication.

It is necessary to consider the complaints often voiced about the seeming injustice that exists when the retail price of a good rises at the very same time that the price received by the farmers or manufacturers who physically make the good falls. For example, the retail price of eggs or potatoes may go up at the very same time that the price of eggs or potatoes received by farmers goes down.

Despite the incredulity often expressed by the news media over such events, there is actually nothing in them that should be surprising or that implies that retailers or wholesalers are somehow exploiting the producers and consumers. This becomes clear when it is realized that the price of a good to its producer constitutes only a portion of the total costs of bringing the good to the consumer. Particularly in the case of inexpensive bulky goods, like potatoes, or goods which require special handling and packaging, like eggs, the price of the good to the producer may well account for less than half of the total cost of bringing the good to the consumer, because other costs, such as transportation and packaging, play such a large role.

In such cases, even though from a strictly physical point of view the product is hardly changed when it reaches the consumer from what it was when it left the producer, the price to the producer represents no greater proportion of the total cost than, say, the price of steel represents in the cost of an automobile. In such cases, a fall in the price of the good to the producer may very well be accompanied by a rise in other components of its total cost that are more than offsetting and thus raise its total cost and necessitate a rise in the retail price of the good. On the basis of the uniformity-of-profit principle, it can be stated with certainty that reductions in the price of goods to producers accompanied by increases in the price of those goods to the ultimate consumers cannot in any circumstances lastingly serve to increase the profits of retailers and wholesalers to a point significantly above what corresponds to the general or average rate of profit. Any increase in the profitability of retailing or wholesaling above the general level would provide the incentive and means for increased investment in those lines and thus a reduction in their profitability back to the general level.⁵⁰

It should be realized that any notion of a constant tendency for prices to producers to fall while retail prices rise is an illusion resulting from continuous inflation of the money supply coupled with the greater volatility of many producer prices in comparison with retail prices. The continuous inflation of the money supply results in

a tendency for all prices to rise. Many producer prices, however (particularly those of agricultural commodities), being highly volatile, frequently rise more rapidly than retail prices. These more rapid increases in producer prices are then followed by periods in which producer prices fall back, while retail prices go on rising. The periods of more rapid increases in producer prices are strangely overlooked by those who complain of the fall in producer prices. Over time, there is no tendency for the rise in retail prices to outstrip the rise in producer prices—unless, for some improbable reason, at the same time that inflation goes on, improvements in the productivity of labor at the producer level continually outstrip improvements in the productivity of labor in retailing and wholesaling and thereby retard the rise in producer prices relative to the rise in prices at the retail level. Even in this case, of course, there would be no tendency for the profits of retailing and wholesaling to rise permanently relative to those of any other segment of the economic system.

4. The Productive Role of Advertising

The fact that in a division-of-labor society the individual produces or helps to produce just one or, at most, a very small number of goods, and is supplied by others with almost everything that he consumes, also underlies the productive role of advertising. Since, in almost every instance, the consumers are separate, distinct persons from the producers, they do not possess any direct, automatic knowledge of what goods are available to them, or of where and from whom and on what terms they are available. The productive role of advertising is to supply this knowledge. In the absence of advertising, the resulting lack of knowledge would be equivalent to a radical reduction in the physical amount of production. This is because the goods and services that people would then be unaware of might as well simply not have been produced, inasmuch as they would be incapable of doing people any actual good in such circumstances.

Furthermore, even when people already know what goods are available and where and on what terms, advertising still has the effect of increasing the amount of benefit that is derived from the same amount of physical production. Advertising accomplishes this by increasing the awareness people have of the availability of various goods and by thus inducing them to try goods they would not otherwise have tried, or tried as soon, which they then discover that they prefer to goods they were previously consuming and would otherwise simply have gone on consuming.

To illustrate this point, we can consider precisely the kind of case that is frequently advanced in order to deny the value of advertising. For example, toothpaste brand

A begins to advertise and, as a result, attracts customers who previously used brands *B*, *C*, *D*, etc.⁵¹ Perhaps, because of the increase in its sales volume, the unit cost of manufacturing brand *A* falls, thereby offsetting, or even more than offsetting, any additional unit cost incurred as the result of the advertising. Now, however, brands *B*, *C*, *D*, etc., begin to advertise. And they win customers from brand *A*. Even if, as the critics of advertising assume, each brand ends up with essentially the same number of customers when all of them advertise as when none of them advertised, and now has higher total costs as the result of the additional cost incurred in order to advertise, and thus must correspondingly raise its price—even so, advertising still provides a major benefit.

This is because now, as the result of advertising, large numbers of individuals use brands that they like better than the brands they had been using and would have gone on using in the absence of advertising. Even though brand *A* may end up with no more customers in toto than it had to begin with, the customers it has gained prefer brand *A* to the various other brands, while the customers it has lost prefer the brands to which they have switched, to brand *A*. In other words, even though every brand may end up with the same number of customers it had in the first place, the customers for each brand are now *different individuals*, who are better satisfied. In this way, because of advertising, there is an increase in the amount of benefit derived from the same physical amount of production.

In this particular case, of course, the selling price of the product would end up being somewhat higher because of the increase in total cost as the result of advertising. But this is no more of an objection against advertising than it would be an objection against the addition of flavoring or any other improvement in toothpaste, such as improved cavity-fighting capabilities, which when they were added increased the total cost and thus the price. It is no objection because the higher cost and higher price are necessary in order to provide worthwhile benefits.

Because of the extent of the ignorance surrounding advertising, it must be pointed out that any addition to total cost that advertising might be responsible for is always strictly limited. It is never the case that producers can go on increasing their advertising budgets endlessly, with the first to make the latest increase being spurred on by the prospect of enlarging his sales volume at the expense of his rivals who have not yet made that increase, with the ultimate result being an endless rise in total costs and prices for products finally consisting of little more than advertising puffery.⁵²

There is such a thing as diminishing returns to advertising. Once a certain degree of awareness of a product is established, additional advertising serves to increase

awareness less and less. Any producer spending excessively for advertising will find himself at the mercy of other producers, who advertise adequately, but less than he does. This is because these producers can then advertise their lower prices, made possible by lower total costs resulting from the avoidance of excessive advertising.

Despite the existence of cases in which advertising provides important benefits in conjunction with a rise in the cost and price of products, its usual effect is to *reduce* prices. It does so by encouraging new competition and the introduction of new and improved products. It encourages new competition by enabling new entrants into an industry to gain exposure in the eyes of the consuming public. In the absence of extensive advertising of new products, people's main guide to what to consume would be personal experience, which necessarily would favor the established firms, since they are the only existing firms with which people have had experience. Extensive advertising, however, allows new entrants into an industry to gain entree into people's awareness alongside of the established firms.⁵³

The effectiveness of advertising in this regard is closely related to the fact that large-scale advertising is usually equivalent to a firm posting a bond with the public, as it were, guaranteeing the value of its product. The equivalence to a bond is based on the fact that advertising usually pays only if, after it induces people to try the product, the product itself is good enough to induce them to buy it again and to recommend it to others. It generally does not pay to advertise products which people will buy only once and then advise others against buying. Products which turn out not to represent a sufficient benefit to the public to induce repeat purchases and recommendations to others usually end up causing a loss of the advertising budgets expended on them.⁵⁴ On this basis, people are right to place confidence in highly advertised products. The advertising not only calls the product to their attention, but also signifies that the producer is willing to risk his money in the conviction that they will like his product.

Advertising reduces prices and promotes the introduction of new and improved products by shortening the period of time required for a product to gain a mass market and thus achieve the economies of large-scale production. In the absence of advertising, good products, it is true, can eventually gain a mass market on the strength of word-of-mouth recommendations; but advertising allows this to happen sooner.

This shortening of the period of time required for a product to establish its market, which advertising achieves, is the more important, the greater are the outlays that must be made in paying for such things as the research and development costs of a product. The longer the

period of time that must elapse between the making of these outlays and their recovery in the sale of the product, the greater must be the sums ultimately recovered, in order to provide the going rate of return on the capital invested in these outlays.

For example, if \$10 million must be invested in outlays for research and development, and 10 years must elapse before those outlays can be recovered in the sale of the product, then, with a going rate of return on capital of 10 percent per year, the sales revenue that needs to be brought in to compensate for these outlays is approximately \$26 million—i.e., \$10 million times 1.1¹⁰. If, on the other hand, advertising can secure a mass market for the product within, say, 1 year, then the sales revenue necessary to compensate for the research and development outlays is only \$11 million—that is, \$10 million times 1.1¹. In this way, advertising reduces the price that it is necessary for a product to sell for in order to yield the going rate of return on its research and development outlays. It thus encourages the making of research and development outlays and the introduction of new products.

In the absence of advertising, there would be products that it would not pay to develop, even if they had the potential eventually to achieve a mass market. This would be because the time required to achieve that mass market would then be so great that the ultimate reduction in manufacturing costs made possible by a mass market would be offset by the increased amount of profit required to provide the going rate of return on the capital invested in the product's research and development outlays. In such cases, a mass market would never actually materialize because the price of the product necessary to provide profitability even in a mass market would be too high for the existence of such a market. In greatly reducing the time required to achieve a mass market, and thus the price that is necessary in order for a product to be profitable in such a market, advertising makes possible the profitable existence of such markets.

In general, and to repeat, advertising promotes research and development outlays and the introduction of the new products that depend on them, by reducing the extent to which such outlays need to be recovered in the price of the product. It does so by means of establishing a larger market sooner rather than later, thereby permitting the recovery of such outlays to take place sooner rather than later and thus with the accompaniment of a correspondingly smaller amount of profit.

Finally, it must be stressed that advertising never dictates what people consume. Advertising influences consumption only in the limited sense that it can make people aware of things that they then decide—on the

basis of their own needs and their own experience with the things advertised—that they like or do not like. Successful advertising is advertising that makes people aware of things which have the power to serve needs that preexist in them. If what is advertised serves no preexisting need in the consumer, then it has no foundation for success.

This explains the well-known fact that it pays to advertise extensively only products that are capable of generating some significant sales even with relatively little advertising. These are the products that advertising can be effective in helping to sell. For example, publishers increase the advertising budgets of those titles that do best with their initial advertising budgets; those are the titles that advertising can help most.

The rule for success is to advertise products of the kind that when tried will be liked and recommended by the buyers. The advertisers have no power over what it is that when tried will be liked and recommended. The advertising of automobiles and electric light in competition with the horse and buggy and candles was highly successful, because people had only to try these new goods in order to appreciate their merit. On the other hand, no amount of advertising of the horse and buggy and candles could have maintained the demand for those goods in the face of the competition of the automobile and electric light.⁵⁵

The notion that the consumers simply do what the advertisers tell them implies an inability to recognize any objective foundation in the choices consumers make. It suggests an intellectual void on the part of the critic of advertising, of such dimensions as to imply that he is an utter stranger to life in the modern world, incapable of understanding the most elementary connections between modern material goods and his own life and well-being.⁵⁶

PART C

BUSINESSMEN AND CAPITALISTS: CLASSICAL ECONOMICS VERSUS THE MARXIAN EXPLOITATION THEORY

1. The Association Between Classical Economics and the Marxian Exploitation Theory

The leading source of the denial of the productive role of businessmen and capitalists and of the hostility to profits and interest is the Marxian exploitation theory. The essential claim of this theory is that all income naturally and rightfully belongs to the wage earners, but

that under capitalism the wage earners receive only bare, minimum subsistence, while everything over and above this is expropriated by the capitalist exploiters in the form of profits, interest, and land rent, or, in the terminology of Marx, “surplus-value.”

In his development of the exploitation theory (which I will describe in detail in Part A of Chapter 14), Marx employs two leading doctrines that are closely identified with classical economics: namely, the labor theory of value and the iron law of wages. I have already referred to the iron law of wages in connection with my discussion of Ricardo’s theory of land rent. It is the doctrine that, broadly speaking, asserts an inescapable connection between wages and minimum subsistence. The labor theory of value claims that the prices of commodities are determined by the respective quantities of labor required to produce them. I will explain both of these doctrines, in the form in which they were propounded by the classical economists, at length, in Sections 4 and 5 of this part. In particular, I will focus on the views of Smith and Ricardo, the two foremost representatives of the classical school, to whom Marx is assumed to be particularly indebted. On the basis of my discussions in these sections, it will be obvious later on, in Chapter 14, that what Marx meant by the labor theory of value and the iron law of wages are two very different sets of ideas than what the classical economists meant, and are in fact gross distortions of what the classical economists meant.

Nevertheless, mainly because of the prominent role played by “the labor theory of value” and “the iron law of wages,” however different their actual content in the two systems of thought, classical economics is almost universally assumed to lead inexorably to the Marxian exploitation theory.

My reason for writing this part, and presenting it here, is that subsequent chapters in this book depend vitally on leading doctrines I have taken over from the classical economists and reintroduced in a modernized form, doctrines which have been abandoned or forgotten precisely because of the mistaken belief that classical economics inevitably leads to the Marxian exploitation theory. As a result, in order to demonstrate the consistency of my profound intellectual indebtedness to classical economics with my unswerving support of capitalism, it is necessary for me to explain the actual nature of the relationship between classical economics and the Marxian exploitation theory, which, I will show, is ultimately one of the most intense opposition.

Consistent with the ultimate opposition that I will demonstrate between classical economics and the exploitation theory, is the fact that I have already reintroduced two abandoned or forgotten doctrines of classical economics with very positive results for the defense of

capitalism: in Chapters 6 and 10, the role of cost of production in determining the prices of most manufactured or processed goods, and, in Part A of this chapter, the essential role of moneymaking in productive activity and the various concepts pertaining to what constitutes production or consumption.⁵⁷ My demonstration that considerations of cost of production rather than elasticity of demand are decisive in price determination under the freedom of competition, played an essential role in my refutation of the profoundly anticapitalistic marginal-revenue, cartel, and pure-and-perfect-competition doctrines in Chapter 10. My elaboration of the concepts pertaining to the connection between moneymaking and productive activity earlier in this chapter have served, among other things, to demonstrate that government spending and government borrowing are inherently consumption, rather than any part of the productive process. This, of course, all by itself implies the need for strict limits on government spending and for the outright prohibition of government borrowing.

Nevertheless, it is certainly true that the Marxian exploitation theory is largely the product of major errors in classical economics, particularly, as I will show, in the writings of Adam Smith. The relationship between classical economics and the exploitation theory represents a tangle of irony and tragedy.

One irony is that while various errors and confusions in classical economics really did contribute to the exploitation theory, the most fundamental and important of these errors and confusions have gone unnoticed and unidentified. These are the errors and confusions pertaining to *the conceptual framework of the exploitation theory*, which assumes that all income due to the performance of labor is wages and that profits are a deduction from what is naturally wages. They have gone unnoticed and unidentified because the validity of this framework is taken for granted—as being literally unexceptionable and therefore unobjectionable. It is assumed to be correct by the opponents of Marx as much as by Marx; this includes Böhm-Bawerk, the leading critic of the exploitation theory, as will be obvious once I have explained the essentials of his critique of the exploitation theory.

A second and greater irony is that the basis for demolishing both the conceptual framework of the exploitation theory and later the whole of the specific substance of the exploitation theory, is provided precisely by essential elements of classical economics. That is, classical economics makes it possible to understand such propositions as why profits, not wages, are the original and primary form of income and that precisely because of the work of businessmen and capitalists, wages can rise out of all connection with minimum subsistence—literally without limit.⁵⁸ I will venture to say, not by the end of Chapter

14, but by the end of the very next section of this chapter, the reader will be able to see how classical economics can be placed so squarely in opposition to the Marxian exploitation theory as literally to serve as the latter's nemesis rather than as its foundation. (Of course, I do not maintain that the classical economists were themselves aware of the implications I am claiming for their doctrines. The development and demonstration of these implications are major accomplishments for which I myself must claim original credit.)

The tragedy of the relationship between classical economics and the exploitation theory has not only been that errors and confusions in classical economics have supported the exploitation theory and thereby the assault on capitalism and advancement of the cause of socialism. That would have been bad enough. The further tragedy and irony has been that because this support was perceived as necessary and inescapable—as based on the essential nature of classical economics—the opponents of the exploitation theory—that is, the defenders of capitalism from the late nineteenth century on, who had the most to gain from the knowledge provided by classical economics—felt obliged to discard virtually the whole of it insofar as it could not immediately be validated on the basis of the neoclassical principle of diminishing marginal utility, or otherwise independently of classical economics' basic framework.

Thus, along with “the labor theory of value” and the “iron law of wages,” they discarded such further features of classical economics as the wages-fund doctrine and its corollary that savings and capital are the source of almost all spending in the economic system. (The wages-fund doctrine held that at any given time there is a determinate total expenditure of funds for the payment of wages in the economic system, and that the wages of the employees of business firms are paid by businessmen and capitalists, out of capital, which is the result of saving; not by consumers in the purchase of consumers' goods.⁵⁹) Two generations later, the abandonment of the wages-fund doctrine and with it, classical economics' perspective on saving and capital, made possible the acceptance of Keynesianism and the policy of inflation, deficits, and ever expanding government spending. In similarly paradoxical fashion, and with just about the same time lag, the abandonment of the classical doctrine that cost of production, rather than supply and demand, is the direct (though not the ultimate) determinant of the prices of most manufactured or processed goods led to the promulgation of the doctrines of “pure and perfect competition,” “oligopoly,” “monopolistic competition,” and “administered prices,” with their implicit call for a policy of radical antitrust or outright nationalizations to “curb the abuses of big business.” Thus, along these two further

paths, the errors of classical economics in support of the exploitation theory have served in the assault on capitalism and to advance the cause of socialism. But this time, it was with the implicit support of those who had abandoned classical economics because of its service in the advancement of socialism, and who now, precisely because of that abandonment, were themselves making possible the advancement of socialism, however much they may have believed themselves to be incapable of acting in such a destructive way.

Indeed, so strong has been the conviction on the part of the defenders of capitalism that classical economics is permeated with support for Marxism, that even to suggest such a classical doctrine as that cost of production can be a direct determinant of price, is to invite one's own censure for allegedly being sympathetic to Marxism—as well as for allegedly being ignorant of all that economics has taught on the subject of prices since 1870. Not surprisingly, in the great majority of cases, this hostility to classical economics on the part of the defenders of capitalism has kept them from any serious study of it.

The essential purpose of this part is to show how classical economics can easily cast off all the aspects of it which contributed to the exploitation theory, while leaving all of its essential and valuable features that were abandoned or forgotten because of its association with the exploitation theory, not only undamaged, but placed in a condition in which they can serve radically to advance the cause of sound, procapitalist economics in the present day. In effect, the purpose of this part is to rescue the classical-economics baby from the Marxist bath water with which he was thrown away, and then, to the extent I have not already done so, raise him up to be the great procapitalist fighting man that it is in his nature to become.

What precise features of classical economics need revision, or outright discarding, will become clear in the next four sections of this part, that is, Sections 2–5. The first of these, a critical analysis of Adam Smith's support of the conceptual framework of the exploitation theory, will go a long way toward proving the claim I made in the Introduction to this book that “classical economics makes possible a far more fundamental and thoroughgoing critique of the exploitation theory than that provided by Böhm-Bawerk and the Austrian school.” Based largely on the results of correcting Smith's errors, Section 3 will name and, to the extent necessary, describe the five major aspects of classical economics in need of revision or discarding in order to transform it into the nemesis of the exploitation theory. Two of these aspects, the labor theory of value and the iron law of wages, will then be examined separately and in detail in Sections 4 and 5 of this part.

2. Correcting the Errors of Adam Smith: A Classical-Based Critique of the Conceptual Framework of the Exploitation Theory

The ideas of Adam Smith on the subject of productive activity are among the best and the worst in the literature of economics. As previously shown, Smith's *Wealth of Nations* provides a major contribution to the understanding of the concept of productive activity in its grasp of the essential connection between productive activity and moneymaking and the role of this connection in the distinction between production and consumption.⁶⁰ Thus, it is not surprising that Smith is the enemy of government spending and government borrowing and that historically his views have been a leading source of fiscal conservatism.⁶¹

But in his discussion of other aspects of the concept of productive activity, Smith's errors are monumental and overwhelming. For in truth, Smith can justly be called the father of the Marxian exploitation theory. Decades before the birth of Marx, he proclaimed the view of businessmen and capitalists, and of capitalism as a system, as parasitically feeding off the labor of the wage earners. Adam Smith, who, more than any other economist, is viewed by the public as the champion of capitalism, was thus in fact the father of the idea that capitalism deserves to be overthrown and replaced by socialism.

Smith's Confusion Between Labor and Wage Earning

A hint of Smith's errors in support of the exploitation theory is present even in one of the passages I quoted favorably in the first part of this chapter: “Thus the labour of the manufacturer adds, generally, to the value of the materials which he works upon, that of his own maintenance, and of his master's profit.” There is a clear suggestion in these words that the labor of the manual worker creates the employer's profit.

This notion is propounded much more forcefully in earlier portions of *The Wealth of Nations*. There, Smith unmistakably expounds the view that the only productive parties in the economic system are wage earners. He clearly regards businessmen, capitalists, and landowners as having no productive function, and as existing as parasites upon the labor of the wage earners.

He begins with the—essentially correct—view that human labor is the fundamental productive agent: “Labour was the first price, the original purchase money that was paid for all things. It was not by gold or by silver, but by labour that all the wealth of the world was originally purchased”⁶² He then goes on to regard *labor and wage earning as synonymous*, and to hold that *all income which is due to the performance of labor is*

wages, and that all who work are wage earners.

He considers and quickly rejects the possibility that profits might be an income attributable to the performance of labor by businessmen and capitalists:

The profits of stock, it may perhaps be thought, are only a different name for the wages of a particular sort of labour, the labour of inspection and direction. They are, however, altogether different, are regulated by quite sufficient principles, and bear no proportion to the quantity, the hardship, or the ingenuity of this supposed labour of inspection and direction. They are regulated altogether by the value of the stock employed, and are greater or smaller in proportion to the extent of this stock. Let us suppose, for example, that in some particular place, where the common annual profits of manufacturing stock are ten per cent. there are two different manufactures, in each of which twenty workmen are employed at the rate of fifteen pounds a year each, or at the expence of three hundred a year in each manufactory. Let us suppose too, that the coarse materials annually wrought up in the one cost only seven hundred pounds, while the finer materials in the other cost seven thousand. The capital annually employed in the one will in this case amount only to one thousand pounds; whereas that employed in the other will amount to seven thousand three hundred pounds. At the rate of ten per cent. therefore, the undertaker of the one will expect a yearly profit of about one hundred pounds only; while that of the other will expect about seven hundred and thirty pounds. But though their profits are so very different, their labour of inspection and direction may be either altogether or very nearly the same.⁶³

Thus, Smith believed, as have so many economists who have come after him, that because profits vary with the amount of capital employed, they cannot be caused by the labor of the businessmen or capitalists—that, instead, they are caused in one way or another by capital itself. I shall deal with this idea shortly. But even here it must be stated that it is blatantly false to maintain, as did Smith, that profits “bear no proportion to the quantity, the hardship, or the ingenuity of this supposed labour of inspection and direction.”

The rate of profit is *not* the same for all enterprises. The amount of profit a firm earns is by no means proportional merely to the quantity of capital it employs. The *ingenuity* of the “supposed labour of inspection and direction” is decisive. Some firms have losses, because insufficient ingenuity is supplied. Others earn an extraordinarily high rate of profit, because more than the ordinary degree of ingenuity is supplied. It is equally true, contrary to Smith, that profits vary with the *quantity and hardship* of the “labour of inspection and direction.” Those firms whose owners “burn the midnight oil,” as the saying goes, generally do better than those whose owners take a more relaxed attitude. But even if all firms did earn the same rate of profit on their capital, their profits, as we shall see, would still be the result of what Smith calls the

“supposed labour of inspection and direction.”

It is even true that profits vary with the quantity and hardship of the businessmen’s and capitalists’ ordinary physical labor. This latter variation is imperceptible in the case of large firms, but it is very evident in the case of small concerns. The neighborhood hardware store, for example, typically earns a much higher rate of profit than a large corporation, precisely because the quantity and hardship of the owner’s physical labor bulks so large in its operations. In all such cases, accountants report the full income of the businessmen and capitalists as profit, and then economists, applying the doctrines of opportunity cost and imputed income, arbitrarily deny that that portion of the profit which obviously does correspond to the owner’s labor *is* profit. They call it wages insofar as wages are what the businessman would receive if he performed similar labor for someone else, or would have to pay to someone else to have similar labor performed for him. Only by first subtracting from profit what in fact is a part of profit, is the obvious variation of profit with the physical labor of businessmen and capitalists eliminated.

The Conceptual Framework of the Exploitation Theory

Having dismissed the possibility that profits could be a labor income, and regarding whatever income might be due to labor as necessarily being wages, Smith arrives at what I consider to be the essential conceptual framework of the exploitation theory. This framework is *the belief that wages are the original and primary form of income, from which profits and all other nonwage incomes emerge as a deduction with the coming of capitalism and businessmen and capitalists*. The framework and its supporting beliefs easily lead to the assertion of the wage earner’s right to the whole produce or to its full value. Thus, Adam Smith opens his chapter on wages, with the following words:

The produce of labour constitutes the natural recompence or wages of labour.

In that original state of things, which precedes both the appropriation of land and the accumulation of stock, the whole produce of labour belongs to the labourer. He has neither landlord nor master to share with him.

Had this state continued, the wages of labour would have augmented with all those improvements in its productive powers, to which the division of labour gives occasion.

And he continues, a little further on:

But this original state of things, in which the labourer enjoyed the whole produce of his own labour, could not last beyond the first introduction of the appropriation of land and the accumulation of stock. It was at an end, therefore, long before the most considerable improvements were made in the productive powers of labour, and it would be to no purpose to trace further what might have been its effects upon the recompence or wages of labour.

As soon as land becomes private property, the landlord demands a share of almost all the produce which the labourer can either raise or collect from it. His rent makes the first deduction from the produce of the labour which is employed upon the land.

It seldom happens that the person who tills the ground has the wherewithal to maintain himself till he reaps the harvest. His maintenance is generally advanced to him from the stock of a master, the farmer who employs him, and who would have no interest to employ him, unless he was to share in the produce of his labour, or unless his stock was to be replaced to him with a profit. This profit makes a second deduction from the produce of the labour which is employed upon land.

The produce of almost all other labour is liable to the like deduction of profit. In all arts and manufactures the greater part of the workmen stand in need of a master to advance them the materials of their work, and their wages and maintenance till it be completed. He shares in the produce of their labour, or in the value which it adds to the materials on which it is bestowed; and in this share consists his profit.⁶⁴

In these passages, Smith actually advances two views that upon examination are astonishing, and which I shall immediately consider in the next two subsections.

Smith's Failure to See the Productive Role of Businessmen and Capitalists and of the Private Ownership of Land

First, he advances the view that the division of labor, and the consequent rise in the productivity of labor, has no connection with the activities of businessmen and capitalists, nor with the institution of private property in land, and might have developed just as well in their absence. This is the meaning of the passage just quoted, "Had this state continued, [i.e., the absence of the appropriation of land and the accumulation of 'stock'—viz., capital], the wages of labour would have augmented with all those improvements in its productive powers, to which the division of labour gives occasion."

In this and the next passage previously quoted, Smith expresses the belief that the only effect of the activities of businessmen and capitalists and of the existence of private ownership of land is that it denies to the wage earners the ability to keep the whole produce of their labor or its full value. He appears totally unaware of all the ways in which the division of labor vitally depends on the activities of businessmen and capitalists and thus could not have developed without them—namely, on their function of creating, coordinating, and improving the efficiency of the division of labor.⁶⁵ He appears equally unaware of the vital contribution to the division of labor made by the institution of private ownership of land, which was demonstrated in earlier portions of this book.⁶⁶ Indeed, he is particularly harsh in his views of landowners. He writes:

As soon as the land of any country has all become private property, the landlords, like all other men, love to reap where they have never sowed, and demand a rent even for its natural produce. The wood of the forest, the grass of the field, and all the natural fruits of the earth, which, when land was in common, cost the labourer only the trouble of gathering them, come, even to him, to have an additional price fixed upon them. He must then pay for the license to gather them; and must give up to the landlord a portion of what his labour either collects or produces. This portion, or what comes to the same thing, the price of this portion, constitutes the rent of land, and in the price of the greater part of commodities makes a third component part.⁶⁷

In this passage, Smith completely overlooks the incalculable contribution to the productivity of labor in agriculture and mining made by the incentives to efficiency and capital accumulation that private ownership and the security of private property provide. He overlooks the fact that the development of the division of labor itself—insofar as it depends on labor being made available for industry and commerce—depends on the rise in the productivity of labor in agriculture and mining brought about on this foundation. In the absence of private ownership of land and the rise in the productivity of labor it brings about in agriculture and mining, the manpower would simply be unavailable for the development of any significant division of labor in industry and commerce, because almost all workers would be required for the production of food.

Smith's error here rests perhaps on a confusion of the privileged position of the British landed aristocracy of his day, which enjoyed a virtual sinecure through such means as entail legislation and protective tariffs, with that of genuine private landowners who possess full rights of ownership and are subject to the full freedom of competition. Otherwise, it is extremely difficult to understand how he could see as the essential consequence of private ownership the charging of prices for what had previously been free, rather than the enormous improvement in the land and its productive powers. This is as naïve an error as it is possible to make with respect to private ownership of land.⁶⁸

The Primacy-of-Wages Doctrine

The second, possibly even more astonishing notion that Smith advances in the passages quoted above is what I call the primacy-of-wages doctrine. This is the doctrine that in a precapitalist economy—the "early and rude state of society"—in which workers simply produce and sell commodities, and do not buy in order to sell, the incomes the workers receive are wages. Wages are the original income, according to Smith. All income in the precapitalist society is supposed to be wages, and no income is supposed to be profit, according to Smith, because work-

ers are the only recipients of income. At the same time, of course, Smith advances the corollary doctrine that profit emerges only with the coming of capitalism and businessmen and capitalists, and is a deduction from what is naturally and rightfully wages.

The primacy-of-wages doctrine and the notion that profits and the other nonwage incomes are a deduction from what is naturally and rightfully wages constitute the conceptual framework of the exploitation theory. They are the starting point for Marx's detailed development of the exploitation theory.

In a precapitalist economy, production, says Marx, is characterized by the sequence C-M-C. In this state of affairs, a worker produces a commodity C, sells it for money M, and then buys other commodities C. In this state of affairs, there is no exploitation, for there are no profits, no "surplus-value"; all income is, supposedly, wages. Surplus-value—profit—emerges only with the development of capitalism, according to Marx. Here the sequence M-C-M' applies. Under this sequence, the capitalist expends a sum of money *M* in buying materials and machinery and in paying wages. A commodity *C* is produced, which is then sold for a larger sum of money, *M'*, than was expended in making it. The difference between the money the capitalist expends and the money he receives for the product is his profit or surplus-value.⁶⁹

Profits, then, according to both Smith and Marx, come into existence only with capitalism, and are a deduction from what naturally and rightfully belongs to the wage earners.

This is not yet the exploitation theory itself, only the conceptual framework of the exploitation theory. The exploitation theory proper, of course, builds on two further doctrines, also largely supplied by Adam Smith—with a major assist from David Ricardo—and then grossly distorted by Marx: namely, the labor theory of value and the "iron law of wages."

A full critique of the exploitation theory, to be sure, needs to deal both with the labor theory of value and with the iron law of wages, and ours shall do so in due course. First, however, what it is essential to show is the enormity of the errors involved in the conceptual framework of the exploitation theory—in the doctrines of the primacy of wages and of the deduction of profits from wages.

A Rebuttal to Smith and Marx Based on Classical Economics: Profits, Not Wages, as the Original and Primary Form of Income

As indicated, classical economics itself provides the basis for demonstrating the enormous errors in the conceptual framework of the exploitation theory. Classical economics implies that it is false to claim that wages are the original form of income and that profits are a deduction from wages. This becomes apparent as soon as we

define our terms along classical lines:

"Profit" is the excess of receipts from the sale of products over the money costs of producing them—over, it must be repeated, *the money costs* of producing them.

A "capitalist" is one who buys in order subsequently to sell for a profit. (A capitalist is one who makes productive expenditures.)

"Wages" are money paid in exchange for the performance of labor—not for the products of labor, but for the performance of labor itself.

On the basis of these definitions, it follows that if there are merely workers producing and selling their products, the money which they receive in the sale of their products is *not* wages. "Demand for commodities," to quote John Stuart Mill, "is not demand for labour."⁷⁰ In buying commodities, one does not pay wages, and in selling commodities, one does not receive wages. What one pays and receives in the purchase and sale of commodities is not wages but *product sales revenues*.

Thus, in the precapitalist economy imagined by Smith and Marx, all income recipients in the process of production are workers. But the incomes of those workers are not wages. They are, in fact, *profits*. Indeed, *all* income earned in producing products for sale in the precapitalist economy is profit or "surplus-value"; no income earned in producing products for sale in such an economy is wages. For not only do the workers of a precapitalist economy earn product sales revenues rather than wages, but also those workers have *zero* money costs of production to deduct from those sales revenues.

They have zero money costs precisely because they have not acted as capitalists. They have not bought anything in order to make possible their sales revenues, and thus they have no prior outlays of money to deduct as costs from their sales revenues. Having made no productive expenditures, they have no money costs.

The profit-difference between sales revenues and zero money costs of production is the full magnitude of the sales revenues. If, for example, one sells a product for \$1,000 and has costs of \$500, resulting from previous outlays of \$500 made in order to bring in the sales revenues, then one's profit is \$500. If one sells a product for \$1,000 and has costs of only \$100, resulting from previous outlays of only \$100 made in order to bring in the sales revenues, then one's profit is \$900. If, going further, one has sales of \$1,000 and costs merely of \$10, resulting from previous outlays merely of \$10 to bring in the sales, then one's profit is \$990. If, going still further, one has sales of \$1,000 and costs of just \$1, resulting from previous outlays of just \$1 to bring in the sales, then one's profit is \$999. If, finally, one's sales are \$1,000, and one's costs are zero, resulting from zero previous outlays to bring in the sales, then one's profit is \$1,000—

the full magnitude of the sales revenues.

Precisely, this last is the situation of the workers in Smith's "early and rude state of society" and under Marx's "simple circulation." Those workers, selling their commodities, not their labor, earn sales revenues, not wages. And precisely because they are not capitalists, and are not employed by capitalists, there is no buying for the sake of selling, and thus there are no money costs to deduct from those sales revenues.

To state matters in Marxist terminology, the M of Marx's simple circulation is, in effect, an M' that has not been preceded by any M to bring it in. This is because in the absence of capitalists, there is no productive expenditure and thus no such prior M . Only with capitalistic circulation does an M appear to be deducted from M' . Hence the full magnitude of the M of Marx's precapitalist, simple circulation is profit.

Thus, in the precapitalist economy, only workers receive incomes, and there are no capitalists and no money capital. But all the incomes that the workers receive are *profits* and none are wages. In the precapitalist sequence C-M-C, *everything* is "surplus-value"—100 percent of the sales revenues and an *infinite* percentage of the zero money capital. In the sequence of capitalistic circulation M-C-M', a smaller proportion of the incomes are "surplus-value."

This same conclusion, that in the precapitalist economy all income is profit, and no income is wages, can be arrived at by way of Ricardo's badly misunderstood proposition that "profits rise as wages fall and fall as wages rise."⁷¹ The wages paid in production, according to Ricardo, are paid by capitalists, out of savings and capital, not by consumers. If, as in the precapitalist economy, there are no capitalists, then there are no wages paid in production, and if there are no wages paid in production, the full income earned in Ricardo's framework must be profits.

Smith and Marx are wrong. Wages are not the primary form of income in production. Profits are. In order for wages to exist in the production of commodities for sale, it is first necessary that there *be capitalists*. The emergence of capitalists does not bring into existence the phenomenon of profit. Profit exists prior to their emergence. The emergence of capitalists brings into existence the phenomena of productive expenditure, wages, and money costs of production.

Accordingly, the profits that exist in a capitalist society are not a deduction from what was originally wages. On the contrary, the wages and the other money costs are a deduction from sales revenues—from what was originally all profit. The effect of capitalism is to create wages and to reduce the relative amount of profits. The more economically capitalistic the economy—the more the

buying in order to sell relative to the sales revenues—the higher are wages relative to sales revenues, and the lower are profits relative to sales revenues.

Thus, capitalists do not impoverish wage earners, but make it possible for people to *be* wage earners. For they are responsible not for the phenomenon of profits, but for the phenomenon of wages. They are responsible for the very existence of wages in the production of products for sale.

Without other people existing as capitalists, the only way in which one could survive in connection with the production and sale of products would be by means of producing and selling one's own products, namely, as a profit earner. But to produce and sell one's own products, one would have to own one's own land, and produce or have inherited one's own tools and materials or the money to buy them. Relatively few people could survive in this way. The existence of capitalists makes it possible for people to live by selling their labor rather than attempting to sell the products of their labor. Thus, between wage earners and capitalists there is in fact the closest possible harmony of interests, for capitalists create wages and the ability of people to survive and prosper as wage earners.

And if wage earners want a larger proportion of income in the form of wages and a smaller proportion of income in the form of profits, they should want a higher economic degree of capitalism—that is, in the terminology of Marx, more M relative to M' . For precisely this represents productive expenditure, wages, and costs being higher, and profits being lower, relative to sales revenues. To achieve such change, what the wage earners require is more and bigger capitalists.

Historical confirmation for the theory I am propounding can be found in F. A. Hayek's Introduction to *Capitalism and the Historians*. There we find such statements as: "The actual history of the connection between capitalism and the rise of the proletariat is almost the exact opposite of that which these theories of the expropriation of the masses suggest. . . . The proletariat which capitalism can be said to have 'created' was thus not a proportion of the population which would have existed without it and which it degraded to a lower level; it was an additional population which was enabled to grow up by the new opportunities for employment which capitalism provided."⁷²

The correct theory, as well as the actual history, is the exact opposite of the doctrine of the primacy of wages.

Curiously, even Adam Smith himself comes close to grasping the true state of affairs, when he writes:

His [the wage earner's] employers constitute the third order, that of those who live by profit. It is the stock that is employed for the sake of profit, which puts into motion the

greater part of the useful labour of every society. The plans and projects of the employers of stock regulate and direct all the most important operations of labour, and profit is the end proposed by all those plans and projects. But the rate of profit does not, like rent and wages, rise with the prosperity, and fall with the declension, of the society. On the contrary, it is naturally low in rich, and high in poor countries, and it is always highest in the countries going fastest to ruin.⁷³

Here the employers, previously depicted as parasitical and virtually functionless, suddenly emerge with plans and projects regulating and directing all the most important operations of labor, for the sake of profit. And not only that, but the rate of profit is held to be lower to the degree that capitalists exist and have accumulated capital. And earlier, Smith has said that “the demand for those who live by wages, it is evident, cannot increase but in proportion to the increase of the funds which are destined for the payment of wages.”⁷⁴ And now we are told that the employers’ capital is the main source of such funds.

But instead of drawing the correct conclusion that the existence of capitalists creates and raises wages and reduces the proportion of total income—viz., national income—which is profit, Smith simply draws a further mistaken anticapitalistic conclusion, namely, that because the rate of profit is lower in a more highly capitalistic economic system, “The interest of this third order, therefore, has not the same connexion with the general interest of the society as that of the other two [viz., the wage earners and landowners].”⁷⁵

Now in fact, in the context in which the rate of profit would be lower in a more highly capitalistic economic system, it would only be the *nominal* rate of profit that would be lower, not the real rate of gain of wealth, which would actually be higher. The interests of the businessmen and capitalists are certainly not opposed to this. And it must be pointed out, incidentally, and will be demonstrated later in this book, that capital accumulation does not cause or presuppose a continually falling rate of profit, but is consistent with an unchanged rate of profit that is sufficiently low. The effect of a still lower rate of profit will be shown to be an *acceleration* in the rate of capital accumulation and economic progress.⁷⁶ Furthermore, it will be shown that there are limits to the fall in the rate of profit, set in part by the more rapid accumulation of capital and wealth themselves that a higher economic degree of capitalism achieves. This is because in achieving a higher rate of capital accumulation and thus more rapid increases in production, a higher economic degree of capitalism tends to be accompanied to an important degree by a more rapid increase in the supply of commodity money, which is an almost inevitable accompaniment of more rapid increases in production in general. This in turn adds something to the rate of profit.⁷⁷

However, the central stumbling block for Smith was his utter confusion of a product sales revenue with the payment of wages. His confusion on this point was so great that he could write: “In some parts of Scotland a few poor people make a trade of gathering, along the sea-shore, those little variegated stones commonly known by the name of Scotch Pebbles. The price which is paid to them by the stone cutter is altogether the wages of their labour; neither rent nor profit make any part of it.”⁷⁸ Had Smith grasped the obvious fact that the price of the stones is a *sales revenue*, not a wage payment, he would have understood the fact that workers who sell products, earn sales revenues and profits, not wages; and that if they have expended no funds for the purpose of producing those products, the sales revenues they earn are entirely profit. These realizations might have enabled him to grasp the incalculably important positive productive contribution that businessmen and capitalists make to the economic well-being of wage earners. Had Adam Smith understood these facts, the subsequent history of the world would have been very different.

Further Rebuttal: Profits Attributable to the Labor of Businessmen and Capitalists Despite Their Variation With the Size of the Capital Invested

In a precapitalist economy, the income of labor is profit, and profit is thus obviously a labor income. In a capitalist economy, too, profit is an income earned by labor—by the labor of businessmen and capitalists.

An earlier portion of this chapter has described the labor of businessmen and capitalists as consisting in the creation, coordination, and improvement in the efficiency of the division of labor.⁷⁹ We have seen that the very fact that the labor of businessmen and capitalists is centered on the division of labor is the reason for its almost total omission from the purview of economists and of people generally, inasmuch as they fail to hold in mind the context of the division of labor and its requirements.

We have also seen how the confusion of labor with wage earning, together with the influence of the opportunity-cost and imputed-income doctrines, has led economists arbitrarily to reclassify profits as wages—precisely in cases in which business and accounting practice clearly recognize income resulting from the performance of labor as profit. (The case of a hardware store owner’s profit being reclassified as wages should be recalled.⁸⁰) Repeating the error of Adam Smith, the practice of economists has been simply to deny application of the term profit to income earned by virtue of the performance of labor and to reserve the word for describing income received on other grounds, principally the mere ownership of capital. Consistent with this practice, most of what the classical economists called profit, and the gen-

eral public and businessmen and accountants still call profit, has come to be called interest by the last several generations of economists.

What underlies the notion that profits are an income based on the ownership of capital rather than on any performance of labor by businessmen and capitalists is the fact, pointed out by Adam Smith, that profits tend to vary with the size of the capital invested, even though the labor of the businessmen and capitalists is “altogether or very nearly the same.” Smith was absolutely correct in showing the variation of profits with the size of the capital invested. Where he was incorrect was in his inference that this fact precluded profits from being attributable to the labor of businessmen and capitalists. The truth is that profits are both an income fully attributable to the labor of businessmen and capitalists *and* tend to vary with the size of the capital invested.

The variation of profits with the size of the capital invested is perfectly consistent with their being attributable to the labor of businessmen and capitalists because such labor tends to be predominantly of an intellectual nature—a work of thinking, planning, and decision making. At the same time, *capital stands as the means by which businessmen and capitalists implement their plans*—it is their means of buying the labor of helpers and of equipping those helpers and providing them with the materials of work. Thus, the possession of capital serves to multiply the efficacy of the businessmen’s and capitalists’ labor, for the more of it they possess, the greater is the scale on which they can implement their ideas. For example, a businessman who thinks of a better way to produce something can apply that better way on ten times the scale if he owns ten factories or ten stores than if he owns only one. The fact that in the one case the same labor on his part leads to ten times the profit as in the other case is perfectly consistent with the whole profit still being attributable to his labor.

The well-known compound variation of profits with the passage of time is also perfectly consistent with the fact that they are the product of the businessmen’s and capitalists’ labor. The relationship of profits to the passage of time derives from the fact that profits vary with the size of the capital invested in any given period of time. If one can earn profits in proportion to one’s capital in any given period of time, then if investment for a longer period is to be competitive, one must earn the profits that one could have earned in the shorter period plus the profits one could have earned by the reinvestment of one’s capital and its profits.

Closely related to the preceding point is the fact that the attribution of profits to the labor of businessmen and capitalists is also perfectly consistent with their simultaneously reflecting such a thing as the general state of time

preference in the economic system (i.e., the preference, other things being equal, for the enjoyment of goods in the nearer future rather than in the more remote future).⁸¹ As Chapter 16 will show, time preference is a factor operating to determine the general or average rate of return on capital.⁸² But the individual businessmen and capitalists then earn or do not earn this general or average rate of return, or a higher or lower rate of return, on the basis of their own individual productive accomplishments.

It should be realized that wages, too, which no one disputes are attributable to the labor of the wage earners, vary with things other than the expenditure of labor by the wage earners—for example, with the state of technology and the supply of capital equipment, and with the demand for and supply of labor. In order for an income to be attributable to labor, it is by no means necessary that the performance of labor be the only factor determining its size. The wages of the average worker in the United States, for example, are higher than those of the average worker in practically every other country because of a higher productivity of labor in the United States. This higher productivity rests on the greater extent of capital accumulation in the United States, which, in turn, is traceable to the greater degree of economic freedom and cultural rationality that has traditionally prevailed in the United States in comparison with other countries. Nevertheless, each individual American worker is still responsible for his own earnings. This is merely a restatement of the principle that income is attributable to labor even though it varies with other factors as well.

Nevertheless, precisely this principle is what Adam Smith contradicts in ruling out profits as an income due to the performance of labor. The principle he adopts is that one cannot attribute a greater effect to an agent if the means which the agent employs are greater and more potent.

His argument actually comes to this: One man pulls the trigger of a pistol, another the firing pin of a cannon; one man digs with an ordinary shovel, another with a steam shovel; one man gives orders to a squad of soldiers, another to an army; one man directs a small concern, another a large concern. In each case, the amount of labor performed by the individual in question may be presumed to be equal. According to the principle of Adam Smith, because the amount of labor is equal in each case, the product or result attributable to the labor is equal in each case.

This, of course, is false, and is a contradiction of Smith’s own doctrine that labor is the sole cause of wealth. This last, sound doctrine rests on the principle that the effect is always to be attributed to *the guiding and directing intelligence that is present*, irrespective of the magnitude and potency of the means employed. (And

irrespective of the presence of all other external circumstances necessary to the outcome, including the existence of such physical phenomena as gravitation and air pressure as well as the existence of the kind of economic and cultural phenomena I described a few paragraphs ago.) If this were not the standard, then it would be impossible to attribute to human beings anything beyond what they could directly and immediately accomplish with their bare hands. One could not only not say that a worker using a steam shovel digs a hole, one could also not say that a worker using an ordinary shovel digs a hole. Indeed, if one applies Smith's principle that variation of the outcome with the magnitude and potency of the means employed precludes its attribution to labor, then his whole argument against profits being due to labor can be parodied as follows:

The holes that are dug, it may perhaps be thought, are only a different name for the products of a particular sort of labour, the labour of digging. They are, however, altogether different, are regulated by quite sufficient principles, and bear no proportion to the quantity, the hardship, or the ingenuity of this supposed labour of digging. They are regulated altogether by the means employed for digging, and are greater or smaller in proportion to the extent of those means. Let us suppose, for example, that in some particular place, there are two different men, one of whom sets about digging with his bare hands; the other of whom employs a shovel. The one man will expect a hole of only very small dimensions, while the other will expect a hole of much larger dimensions. But though the holes that are dug are so very different, their labour of digging may be either altogether or very nearly the same.

The variation of profits with the size of the capital in no way contradicts the fact that profits are a labor income. Equal labor does *not* produce equal products. It produces unequal products when unequal means are employed. It is always labor which produces, however, because it is labor which supplies the guiding and directing intelligence in production.

It must be stressed: guiding and directing intelligence, not muscular exertion, is the essential characteristic of human labor, and the basis for attributing all production to labor. As von Mises says, "What produces the product are not toil and trouble in themselves, but the fact that the toiling is guided by reason."⁸³

On this basis, *all* labor is the "labour of direction." It is because the man directs the tool, that he, and not the tool, produces the product. The tool, whether an ordinary shovel, a steam shovel, dynamite, or an atomic explosive, does not produce, but is the *means* by which the man who employs it produces—in precisely the same sense that it is not a gun which can commit murder or an automobile which can commit manslaughter, but the man who pulls the trigger of the gun or the man who drives the automobile.

A Radical Reinterpretation of "Labor's Right to the Whole Produce"

Guiding and directing intelligence in production is supplied by businessmen and capitalists on a higher level than by wage earners—a circumstance which further reinforces the primary productive status of profits and profit earners over wages and wage earners.

The socialists, indeed, have so little conception of the essential role of guiding and directing intelligence in production, that while they claim the product for the manual workers in one breath, they complain in the very next breath of the manual worker's "alienation" from the product. The manual worker does not know, see, or touch the final product, they complain. Capitalism, they say, confines the worker to a narrow task. It limits his horizon to the job immediately at hand—to a tiny step in his firm's overall productive operations.⁸⁴

Now although the division of labor and capitalism are not in fact responsible for "alienation," it is true that the manual worker is necessarily concerned with only a small step in his firm's overall productive operations. For this very reason, it is absolutely impossible that he could be responsible for its products—that the products could legitimately be said to be *his* products. The socialists evidently believe that a product emerges out of *chaos*—as a result of the fortuitous interaction of the operations of people engaged in unintegrated, totally isolated steps in its production. They simply do not see the role of businessmen and capitalists in coordinating and improving the efficiency of the division of labor—or in creating the division of labor in the first place.

The fact that profits are an income attributable to the labor of businessmen and capitalists, and the further fact that their labor represents the provision of guiding and directing intelligence at the highest level in the productive process, requires a radical reinterpretation of the doctrine of labor's right to the whole produce. Namely, that that right is satisfied when first the full product and then the full value of that product comes into the possession of *businessmen and capitalists*, for *they*, not the wage earners, are the fundamental producers of products. The employees of the firm are accurately described by the common expression "help." They are the helpers of the businessmen and capitalists in the production of *their*—the businessmen's and capitalists'—products. It should be obvious that thus understood, the realization of labor's right to the whole produce is exactly what occurs in the everyday operations of a capitalist economy, inasmuch as it is businessmen and capitalists who are the owners first of the products and then of the sales proceeds received in exchange for the products.

By the standard of attributing results to those who conceive and execute their achievement at the highest

level, one must attribute to businessmen and capitalists the entire gross product of their firms and the entire sales receipts for which that product is exchanged. Such, indeed, is the normal standard in fields other than economic activity. For example, one attributes the discovery of America to Columbus, the victory at Austerlitz to Napoleon, the foreign policy of the United States to its President. These attributions are made despite the fact that Columbus could not have made his discovery without the aid of his crew, nor Napoleon have won his victory without the help of his soldiers, nor the foreign policy of the United States be carried out without the aid of the employees of the State Department. The help these people provide is perceived as the means by which those who supply the guiding and directing intelligence at the highest level accomplish *their* objectives. The intelligence, purpose, direction, and integration flow down from the top, and the imputation of the result flows up from the bottom.

By this standard, the products of the old Ford Motor Company and Standard Oil Company are to be attributed to Ford and Rockefeller. (In many cases, of course, the product must be attributed to a group of businessmen and capitalists, not just to a single outstanding figure.) In any event, labor's right to the full value of its produce is fully satisfied precisely when a Ford or Rockefeller, or their lesser known counterparts, are paid by their customers for *their* products. The product is theirs, not the employees'. The help the employees provide is fully remunerated when the producers pay them wages.

Implications for the Incomes of "Passive" Capitalists

The fact that profits, not wages, are the original and primary form of income, and that labor's right to the whole produce is satisfied when businessmen and capitalists receive the sales proceeds, leads to a very different view than Adam Smith's of the payment of incomes to capitalists whose role in production might be judged to be passive, such as, perhaps, most minor stockholders and many recipients of interest, land rent, and resource royalties. Adam Smith has committed the double confusion of putting the wage earner in the place of the seller of products, and thus of businessmen and capitalists, and of lumping the active businessmen and capitalists in with the passive capitalists. He believes, in effect, that the workers on Henry Ford's assembly line pay him his profit and pay the dividends and interest to the other suppliers of the firm's capital. The fact is, of course, that it is businessmen and capitalists such as Ford who pay both the men on the assembly line *and* any passive recipients of dividends and interest, etc.

If the payment of such incomes did represent an exploitation of labor, therefore, it would not be an exploi-

tation of the labor of wage earners. The wage earners are totally out of the picture. The incomes of the passive capitalists are paid by *businessmen*—by the active capitalists—not by the wage earners. They are not a deduction from wages, but from the profits of the active capitalists. If any exploitation were present here, it would be the active capitalists, not the wage earners, who were the exploited parties. What this would mean in practice is that individuals like Ford and Rockefeller would be exploited by widows and orphans, for it is such people who largely make up the category of passive capitalists.

In fact, however, the payment of such incomes is never an exploitation, because their payment is a source of gain to those who pay them. They are paid in order to acquire assets whose use is a source of profits over and above the payments which must be made. Furthermore, the recipients of such incomes need not be at all passive; they may very well earn their incomes by the performance of a considerable amount of intellectual labor. Anyone who has attempted to manage a portfolio of stocks and bonds or investments in real estate should know that there is no limit to the amount of time and effort that such management can absorb, in the form of searching out and evaluating investment possibilities, and that the job will be better done the more such time and effort one can give it.

In the absence of government intervention in the form of the existence of national debts, loan guarantees, and insurance on bank deposits, the magnitude of truly passive income in the economic system would be quite modest. This is because most forms of investment require the exercise of some significant degree of skill and judgment. Those not able or willing to exercise such skill and judgment would either rapidly lose their funds or would have to be content with very low rates of return in compensation for safety of principal and, in many cases, would have to bear the expense of the deduction of management fees by trustees or other parties.

It should also be realized that in a *laissez faire* economy, without personal or corporate income taxes (a real exploitation of labor) and without legal restrictions on such business activities as insider trading and the award of stock options, the businessmen and active capitalists are in a position to own an ever increasing share of the capitals they employ. With their high incomes they can progressively buy out the ownership shares of the passive capitalists.

In this way, under capitalism, those workers—the businessmen and active capitalists—who do have a valid claim to the ownership of the industries *in fact come to own them*. Again and again, penniless newcomers appear on the scene and by virtue of their success secure a growing influence over the conduct of production and

ultimately obtain the ownership of vast personal fortunes. An ironic consequence of Adam Smith's errors in this area, to be counted among all the other absurdities of socialism, is that the socialists want to give the ownership of the industries *to the wrong workers!* And to do so, they want to destroy the economic system which gives it to the right workers. They want to give it to the manual laborers, while capitalism gives it to those who supply the guiding and directing intelligence in production.

Not surprisingly, the socialists and their fellow travelers, the contemporary "liberals," denounce capitalism's giving ownership to the right workers. They denounce it when they denounce large salaries and stock options for key executives.⁸⁵

Acceptance of the Conceptual Framework of the Exploitation Theory by Its Critics

The enormous flaws in the conceptual framework of the exploitation theory have completely escaped the attention of the theory's critics. Instead, the critics have devoted their attention entirely to the doctrines of the labor theory of value and the iron law of wages. This has been the case because, as I have already pointed out, the critics share that very same conceptual framework. They too accept the notion that wages are the original and primary form of income and that profits (which they often call originary interest) represent a deduction from wages. Where they differ from Marx is in arguing that profits represent a just, rather than an unjust, deduction from wages.

Thus Böhm-Bawerk, the leading critic of the exploitation theory, argues that profits are a justified deduction from wages on the grounds that the capitalists pay the workers in advance of the sale of the products that the workers produce. This fact, in conjunction with the operation of time preference, Böhm-Bawerk holds, enables and entitles the capitalists to pay wages that represent a discounted present value of the wage earners' future product. Later, when the product is completed and sold, the capitalists sell it at its full, then present value.

A leading example of Böhm-Bawerk's views is his famous illustration of five workers cooperating in the production of an engine that requires five years to complete, from the making of tools for the mining of iron ore to the assembly of the various components that make up the engine. In this example, Böhm-Bawerk assumes that the completed engine will sell for \$5,500 and that the five workers each perform labor of equal quantity and skill. The only difference between the workers is that the worker who completes his work at the end of the first year must wait four years to receive his share of the proceeds, while the worker who completes his work at the end of the fifth year will be paid immediately, with

all the other workers having to undergo waiting times between these two extremes.

The fact of unequal waiting times, says Böhm-Bawerk, will lead the workers to make an unequal division of the engine's value. The worker who completes his work at the end of the first year, and who must therefore wait four years to be paid, will receive more than the mere one-fifth of its value that his equal labor would otherwise entitle him to. Instead of \$1,100, he will receive, Böhm-Bawerk imagines, \$1,200. By the same token, the worker who completes his work at the end of the fifth year, and who thus need not wait at all to be paid following completion of his work, will receive only \$1,000. The other three workers will receive various amounts between these two limits.⁸⁶

This, Böhm-Bawerk says, is an unequal division of the engine's value that the workers themselves would make because of the fact that present goods are subjectively more valuable than future goods of the same kind and number. Because of this fact, an equal sum received immediately upon completion of work is more valuable than the same sum that is not to be received until one to four years later. If the workers received the same sums of money, those who performed their labor earlier and who had to undergo correspondingly more waiting time would receive a subjectively smaller value than the workers who performed their labor later and who thus had to undergo less or even no subsequent waiting time at all. On this basis, Böhm-Bawerk argues, \$1,200 received four years after the completion of one's work is no more than the equivalent of \$1,000 received immediately upon completion of one's work.⁸⁷

Having thus set the stage, Böhm-Bawerk now introduces a capitalist. The existence of the capitalist makes it possible for each of the five workers to be paid immediately upon completion of his work. Because of this, in Böhm-Bawerk's view, the just wage of each of these workers, is \$1,000—the same as that of the worker who completes his work last and who by the workers' own presumed standards of justice would have been paid only \$1,000.⁸⁸

In this way, according to Böhm-Bawerk, profits emerge as a just deduction from what would otherwise rightfully all belong to the wage earners. The capitalist pays to the worker who completes his work at the end of the first year the sum of \$1,000, which is the present equivalent of the \$1,200 that worker would otherwise have had to wait four years to receive. He pays \$1,000 to the next worker, who completes his work at the end of the second year and who would otherwise have had to wait three years to receive \$1,150. And so on. Thus, the capitalist pays to the first four workers the present, discounted value of their share in the future product, takes over from them the activity of waiting, and, ultimately, when what

began as a prospective future product becomes an actual present good, sells that good at its full undiscounted, present value. In sum, in buying the labor to produce a product worth \$5,500 with wage outlays totaling \$5,000, the capitalist has paid the present, discounted value of a future good, the rights to which he thereby acquires, and which then ripens, as it were, into a present good in his possession that sells at its full, undiscounted, present value.

For all of its ingeniousness, Böhm-Bawerk's exposition concedes the notion that the starting point of analysis is a valid claim of wage earners to the full value of the product and that profits are a deduction from what was originally all the income of wage earners. These concessions are totally unwarranted. To be accurate, his account would have had to describe the five workers as initially producing separately, on a hand-to-mouth basis, with no possibility of mutual cooperation in the production of any such time-consuming product as an engine. Each of the workers would also have had to be described as selling a product and earning a profit income, not a wage income, and as having to own or produce his own tools and materials in order to do so. The possibility of living by the sale of one's labor in the process of producing products for sale would have had to be described as nonexistent in the face of the absence of capitalists. The role of the businessman/capitalist would then have had to be described as creating and organizing the vertical division of labor among these workers that is necessary for the production of such a time-consuming product as an engine, and of making it possible for them to live as wage earners. The engine itself would have had to be presented as the product primarily of the businessman and capitalist, who provides the guiding and directing intelligence in its production. It would also have had to be pointed out that the proportion of profits in the value of the engine is lower than the proportion of profits in the production of the hand-to-mouth goods produced by the manual workers on their own, and that the proportion constituted by wages is correspondingly higher.

Böhm-Bawerk, of course, did none of these things. Instead, along with his attempt to demonstrate the justice of the deduction of profits from wages, he concentrated his fire on the labor theory of value.⁸⁹ And because the labor theory of value was generally perceived as the essential element both in the exploitation theory and in classical economics, the unfortunate consequence of Böhm-Bawerk's critique was to do as much damage to the prestige of classical economics as to the prestige of Marx.

3. Necessary Revisions in Classical Economics

I have shown that while Adam Smith is the father of the Marxian exploitation theory—in providing its con-

ceptual framework—essential propositions of classical economics can be applied to the total demolition of that framework. This is true in particular of J. S. Mill's proposition that "demand for commodities is not demand for labour" and Ricardo's proposition that "profits rise as wages fall and fall as wages rise."⁹⁰ (Ricardo's proposition, of course, must be taken on the understanding that it is capitalists, not consumers, who pay wages.)

There are five revisions that need to be made in the body of classical economics to transform it from a source of support for the exploitation theory into a source of complete and total opposition to the exploitation theory. Three of these I have already made.

The first revision, accomplished in the last section, is the consistent application of Mill's and Ricardo's propositions. From this comes the recognition that in the conditions of the "early and rude state of society" assumed by Adam Smith, all income is actually profit, not wages. The further recognition also follows that wages come into being with the emergence of capitalists, and are the greater relative to profits, the more economically capitalistic is the economic system. By "economically capitalistic" is meant the extent to which buying for the purpose of selling—productive expenditure—takes place relative to sales proceeds. In other words, wages are higher and profits are lower precisely to the degree that Marx's "*M*" is larger relative to his "*M*'."

The second necessary revision is the recognition of the positive productive functions of businessmen and capitalists and of the fact that they are the fundamental producers of products, inasmuch as they provide the guiding and directing intelligence in production at the highest level—and of the further fact that the variation of profits and interest with the size of the capital invested in no way contradicts these incomes being attributable to the labor of businessmen and capitalists. The result of this revision is the realization that labor's right to the whole produce is satisfied everyday in a capitalist economy—when businessmen and capitalists receive the proceeds from the sale of *their* products. This revision too was accomplished in the present chapter, largely in the last section.⁹¹

The third necessary revision, accomplished in Chapter 9, is consistent recognition of the role of private ownership of land in raising the productivity of labor in agriculture and mining. This leads to the conclusion that private ownership of land underlies the growth of the division of labor, by making labor available for industry and commerce. It also leads to the conclusion that private ownership of land operates to reduce the economic significance of land rent and thus to enlarge the relative share of "national income" that takes the form of wages, and, still more importantly, to help make possible a

continuous rise in the purchasing power and thus the real income of the average wage earner.⁹²

All of these revisions are in accord with the fundamental spirit of classical economics, which stands in defense of private property rights and proclaims the harmony of the rational self-interests of all men. The first and third revisions and their derivatives merely represent making classical economics more self-consistent, while the second fills in a major conceptual gap in the classical system, which was largely ignorant of the productive functions of businessmen and capitalists and largely ignored the essential aspect of guiding and directing intelligence in labor.

The fourth and fifth revisions concern two further doctrines of classical economics, which, as I have shown, usually bear the weight of the accusation that it supports the exploitation theory—namely, the labor theory of value and the “iron law of wages.” For after laying down the conceptual framework he has borrowed from Adam Smith, it is these two doctrines that Marx applies to explain the extent of the alleged deduction of profits from wages. (Usually, Marx uses the term “surplus-value” in place of profits, as a catchall for all incomes other than wages.)

In the next section, I will show that the labor theory of value, as propounded by Ricardo—the classical economist who is most closely associated with it—can easily be restated in a way that not only lends no support to the exploitation theory, but, indeed, helps to provide still further criticisms of the exploitation theory. I will show that it is only the so-called iron law of wages that needs to be thoroughly discarded, and that precisely a proper understanding of the labor theory of value provides one of the leading bases for discarding it.

4. The Labor Theory of Value of Classical Economics

The labor theory of value of the classical economists held that the relative quantities of labor required to produce goods is usually the major determinant of their relative exchange values. The labor in question is all the labor directly or indirectly necessary to the production of a good. For example, in the case of an automobile, this would be the labor performed not only in the auto plants, but also in the production of the steel necessary to make the automobile, and in the production of the iron ore necessary to produce the steel. It would also include the relevant portion of the labor required to make the automaking machinery and to build the automobile factory, the relevant portion of the labor required to make the steelmaking equipment and to build the steel mill, and so on. (The relevant portion of the labor in these last cases would be construed as the fraction of the total labor required to produce these things that corresponds to the

production of just one automobile. For example, if ten million man-hours were required to construct a machine that would last for ten years and that would do nothing but contribute to the production of one million automobiles in each of those years, then the relevant portion of that labor entering into the production of one automobile as the result of the use of that machinery would be one man-hour.)

According to the classical economists, the relative prices of, for example, automobiles, motorcycles, bicycles, and roller skates would then reflect the respective relative quantities of labor required to make these goods. If, for example, it required, all in all, a thousand man-hours to make an automobile, a hundred man-hours to make a motor cycle, ten man-hours to make a bicycle, and one man-hour to make a pair of roller skates, then the relative values of these goods would be in the same ratios—namely, 1,000:100:10:1. Under a system of commodity money, the labor theory of value would apply to the determination of actual, absolute prices, as well as relative exchange values. Thus, if the monetary unit were an ounce of gold, and it required all in all, say, a hundred man-hours to produce an ounce of gold, then the money price of the automobile we have just considered would be 10 ounces, that of the motorcycle 1 ounce, that of the bicycle .1 ounce, and that of the roller skates .01 ounce.

Now I want to say that I myself believe that the quantity of labor required to produce a good is almost always a very important factor determining its price. The best evidence for this proposition is the fact that the use of labor-saving machinery makes goods more affordable. The greater the extent to which machinery reduces the quantity of labor required to produce goods, the less expensive do goods become. Such a result would not be possible if the quantity of labor required to produce goods did not have a significant connection with their price.

Harmonization of the Labor Theory of Value With Supply and Demand and the Productive Role of Businessmen and Capitalists

The recognition of the role of the quantity of labor required in the production of goods as an influence on their price does not preclude the recognition of a variety of other factors as well, nor does it imply that the quantity of labor required in production is always an influence on price. Indeed, properly understood, recognition of the role of the quantity of labor is compatible with the recognition both of supply and demand as the determinant of prices and of the role of businessmen and capitalists in raising the standard of living of the average wage earner!

To combine these three elements of understanding—that is, the quantity of labor required to produce goods,

supply and demand, and the productive role of businessmen and capitalists—all we need do is this: First, realize that the reduction in the quantity of labor required to produce goods makes it possible for the same total quantity of labor in the economic system to produce a larger supply of goods, and thus to increase the supply of goods relative to the supply of labor. Next, realize that this, in turn, implies a fall in prices relative to wage rates, and thus a rise in the buying power and standard of living of the average worker. Then, realize that what brings all this about is precisely the productive activities of the businessmen and capitalists! They, together with scientists and inventors, whose work they continuously seek out and inspire, bring about the steady reduction in the quantity of labor required to produce goods, thus the steady increase in the supply of goods relative to the supply of labor, and thus a steady fall in prices relative to wage rates—viz., a steady rise in real wages. Furthermore, this relationship between the reductions achieved by businessmen and capitalists in the quantity of labor required to produce goods, and the rise in real wages, can be understood in a precise, quantitative way, using the classical economists' concepts of demand and supply as a ratio of expenditure to quantity sold.⁹³

For example, a halving of the quantity of labor required to produce the average good in the economic system, would permit a doubling of the production of goods with the employment of the same total quantity of labor, and thus result in a halving of prices on the assumption that the quantity of money and volume of spending to buy goods in the economic system remained the same. Since there is no increase in the supply of labor present, the existence of a constant quantity of money and a correspondingly fixed aggregate demand for labor implies that the average level of money wage rates remains the same while the prices of goods fall in half, because the same total spending for labor continues to purchase the same total supply of labor.

What we have here, in fact, is precisely the state of affairs that Adam Smith thought would have been possible only under the continuation of his "original state of things," viz., the absence of private ownership of land and the accumulation of capital, but which in fact is possible only with the presence of these things, under capitalism. As previously quoted, Smith wrote: "Had this state continued, the wages of labour would have augmented with all those improvements in its productive powers, to which the division of labour gives occasion. All things would gradually have become cheaper. They would have been produced by a smaller quantity of labour . . ." ⁹⁴ This steady rise in real wages owing to the steady reduction in the value of the commodities that the wages purchase *is exactly what happens under cap-*

italism—as the result of businessmen and capitalists continuously finding ways to reduce the quantity of labor required to produce any given unit of goods and thus to increase the supply of goods relative to the supply of labor.

Other Classical Doctrines and the Rise in Real Wages

It should be realized that this account of the rise in real wages brought about by the businessmen and capitalists incorporates not only the role of quantity of labor required in the production of goods as a factor determining their prices, and the classical concepts of demand and supply, but no less the so-called wages-fund doctrine and Ricardo's doctrine of the distinction between "value and riches." It incorporates the wages-fund doctrine in its implication of a distinct and given demand for labor.⁹⁵ It incorporates the doctrine of the distinction between value and riches in its perception of the rise in real wages as proceeding not from a rise in money incomes, which represents merely an increase in an aggregate monetary value, but from a fall in prices, which is the natural consequence of a greater ability to produce—viz., of greater "riches."⁹⁶ Along the very same lines as the distinction between value and riches, it should also be realized that our assumption that the quantity of money and volume of spending remain the same is consistent with the procedure of the classical economists, especially Ricardo, of assuming the value of money to be constant as far as changes on the side of money itself are concerned, and thus all changes in prices to reflect changes on the side of goods other than money.⁹⁷

Classical Economics' Limitations on the Labor Theory of Value

The classical economists, Ricardo in particular, were well aware of the limitations of the labor theory of value as an explanation of prices.

i. Exclusion of Scarce Goods

According to Ricardo, there was a substantial category of goods to which the labor theory of value did not even apply. Thus, he wrote:

There are some commodities, the value of which is determined by their scarcity alone. No labour can increase the quantity of such goods, and therefore their value cannot be lowered by an increased supply. Some rare statues and pictures, scarce books and coins, wines of a peculiar quality, which can be made only from grapes grown on a particular soil, of which there is a very limited quantity, are all of this description. Their value is wholly independent of the quantity of labour originally necessary to produce them, and varies with the varying wealth and inclinations of those who are desirous to possess them.⁹⁸

In order for the labor theory of value to be made

consistent with Austrian economics and the case for capitalism, it is necessary explicitly to enlarge the list of exceptions whose value is determined by their “scarcity alone.” The necessary enlargement must include all the items whose prices I described back in Chapter 6 as being determined by supply and demand rather than cost of production, either on a permanent or temporary basis.⁹⁹ The most important addition to the list of exceptions, of course, is the value of human labor itself, both skilled and unskilled. This exception, it should be noted, is clearly called for by classical economics itself insofar as the latter upholds the wages-fund doctrine, according to which wage rates are determined by the ratio of the wages fund (viz., the demand for labor) to the supply of labor. Indeed, practically all of these additions to the list of items whose price is not determined either by cost of production or by quantity of labor required in their production, would have been fully acceptable to Ricardo, who, in fact, explicitly notes them.¹⁰⁰ As we shall see in the next section, only in the case of labor would Ricardo have registered any objection—an objection that is confined to special circumstances and then is thoroughly confused.¹⁰¹

ii. Ricardo’s Recognition of the Time Factor as an Independent Determinant of Relative Value

Where the labor theory of value applies, according to Ricardo, is in the production of “such commodities only as can be increased in quantity by the exertion of human industry, and on the production of which competition operates without restraint.”¹⁰² And even in these cases, Ricardo points out, not only is the connection often confined to long-run, equilibrium prices rather than to the market prices that prevail at any given moment, but the long-run equilibrium prices themselves are subject to the operation of another very important factor. He introduces this factor with a section heading in his chapter “On Value,” namely, the heading of Section 4, which reads, “The principle that the quantity of labour bestowed on the production of commodities regulates their relative value considerably modified by the employment of machinery and other fixed and durable capital.”¹⁰³

The modification Ricardo has in mind is the principle that “*commodities which have the same quantity of labour bestowed on their production will differ in exchangeable value if they cannot be brought to market in the same time.*”¹⁰⁴ He illustrates the principle with the following example:

Suppose I employ twenty men at an expense of 1000 pounds for a year in the production of a commodity, and at the end of the year I employ twenty men again for another year, at a further expense of 1000 pounds in finishing or perfecting the same commodity, and that I bring it to market at the end of two years. If profits be 10 per cent., my

commodity must sell for 2310 pounds; for I have employed 1000 pounds capital for one year, and 2100 pounds capital for one year more. Another man employs precisely the same quantity of labour, but he employs it all in the first year; he employs forty men at an expense of 2000 pounds, and at the end of the first year he sells it [his commodity] with 10 per cent. profit, or for 2200 pounds. Here, then, are two commodities having precisely the same quantity of labour bestowed on them, one of which sells for 2310 pounds—the other for 2200 pounds.”¹⁰⁵

A more extreme illustration of the same point is the case of aged wine or whiskey. To earn a 10 percent compound annual rate of profit in the production of whiskey that takes eight years to age, \$1,000 of capital paid out as wages must result in a product that sells for approximately \$2,000, while to earn the 10 percent annual rate of profit in the production of a commodity in which only one year elapses between the outlay of capital and the sale of the commodity, the commodity need sell for only \$1,100. Here is a case in which two equal capitals employ two equal quantities of labor, and yet the one product has an equilibrium price of almost twice that of the other product—because of the influence of the different periods of time for which the rate of profit must be compounded.

Ricardo’s examples concerning the effect of the use of machinery and buildings are too complex to bear quoting. But the following, I think, clearly represents his meaning. Imagine two cases in which \$1,000 of capital is expended in the payment of wages to the same quantity of labor. Once again, assume that the annual rate of profit is 10 percent. In the one case, the product is an item that will be sold one year later. In the other case, it is a machine that will be used in production over a period of ten years. The item to be sold one year after the outlay of wages will have to sell for \$1,100 in order to earn the 10 percent rate of profit. But the machine will have to bring in over the course of its life a sum of at least \$1,500. One hundred dollars must be recovered in each of the ten years in the form of depreciation on the machine. Beyond that, in each of the ten years the further sum of \$50 must be earned as profit on the average capital outstanding in the machine, which is \$500. Thus, in the one case the same quantity of labor results in the production of a product worth \$1,100, while in the other it results in the production of a series of services worth \$1,500.¹⁰⁶

In a letter to his follower and popularizer J. R. McCulloch, Ricardo named the essential point as follows:

Strictly speaking then the relative quantities of labour bestowed on commodities regulates their relative value, when nothing but labour is bestowed upon them, and that for equal time. When the times are unequal, the relative quantity of labour bestowed on them is still the main ingredient which regulates their relative value, but it is not

the only ingredient, for besides compensating for the labour, the price of the commodity must also compensate for the length of time that must elapse before it can be brought to market. All the exceptions to the general rule come under this one of time¹⁰⁷

In the same letter, he even went so far as to write: "I sometimes think that if I were to write the chapter on value again which is in my book, I should acknowledge that the relative value of commodities was regulated by two causes instead of by one, namely, by the relative quantity of labour necessary to produce the commodities in question, and by the rate of profit for the time that the capital remained dormant, and until the commodities were brought to market."¹⁰⁸

iii. Ricardo's Implicit Recognition of Changes in the Rate of Profit as a Further Determinant

Ricardo, in fact, implicitly acknowledges *changes in the rate of profit* as still a further cause of variations in the relative value of commodities. This fact is not as clear as it might be, because he constantly couples a change in the rate of profit with a change in wages. He reasons in a context in which the total monetary value of consumers' goods is fixed and is equal to a sum of total profits and total wages. In this context, every change in the amount of profits is necessarily accompanied by an equivalent opposite change in the amount of wages. At the same time changes in the amount of profits produce changes in the average rate of profit. As a result of this, when total wages rise and total profits and the average rate of profit fall, the effect is to raise the price of some commodities and lower the price of other commodities, even though there has been no change in the quantity of labor required to produce any of them. In Ricardo's words: "Every rise of wages, therefore, or, which is the same thing, every fall of profits, would lower the relative value of those commodities which were produced with a capital of a durable nature, and would proportionally elevate those which were produced with capital more perishable. A fall of wages would have precisely the contrary effect."¹⁰⁹

To understand this point, let us imagine an economic system with a fixed quantity of money and a fixed total volume of spending for consumers' goods of 1,000 units of money per year. Let us further imagine that initially total wages are 800 units of money per year and total profits are 200 units of money per year. The wages on average are paid one year in advance of the sale of the consumers' goods the wage earners help to produce. We can assume that total capital in the economic system is the 800 units of money expended in paying wages, and thus that the average rate of profit in the economic system is 25 percent (the 200 amount of profit divided by the 800 amount of wages, which represents the capital em-

ployed). Now wages rise to 900 and profits fall to 100. The rate of profit accordingly falls to approximately 11 percent ($\frac{100}{900}$).

Ricardo's conclusion becomes apparent if we consider the effect on the prices of goods in which the outlay of wages takes place less than one year in advance of the sale of the resulting product and the effect in cases in which the outlay of wages takes place more than one year in advance of the sale of the resulting product. Thus, imagine a good which initially requires an outlay of 8 of wages and which is sold six months later at a price of 9, which will be the case when the annual rate of profit is 25 percent and thus the semiannual rate of profit is 12.5 percent. The wage outlay for this good now rises to 9. Since the annual rate of profit has fallen to $\frac{1}{9}$, the semiannual rate of profit is $\frac{1}{18}$. The price of this good therefore rises from 9 to 9.5, for it now equals a wage outlay of 9 plus a profit of $\frac{1}{18} \times 9$. But at the same time, the price of a good in whose production the wages must be paid two years in advance of the sale of the good, will actually fall. Here the fall in the rate of profit will outweigh the rise in wages. For example, when the rate of profit was 25 percent, a good requiring an outlay of 8 of wages and selling two years later, would have to sell for 12.5. Now the outlay of wages is 9, but the good only sells for a little over 11, or to be precise, $9 \times (10/9)^2$.

Thus, as noted, Ricardo is aware of the fact that a change in the rate of profit results in a change in relative prices, with no change in the relative quantities of labor required to produce the various goods. The rate of profit, along with the relative periods of time that must elapse between outlays of capital and the sale of the resulting products, is a determinant of the relative value and prices of commodities, according to Ricardo.

In my judgment, Ricardo's development of the influence of time and the rate of profit on the relative value and prices of commodities is in some respects more insightful even than Böhm-Bawerk's. Certainly, after reading Sections 4–6 of his chapter "On Value," there is every reason to believe that he would have been fully in accord with all of the essential points of Böhm-Bawerk's critique of the exploitation theory, especially as presented in *Karl Marx and the Close of His System*.¹¹⁰ For the substance of Böhm-Bawerk's critique in that essay is merely that the fact that the value of commodities varies with the period of time for which profits compound on capital makes it impossible that they should vary exclusively in accordance with the quantity of labor expended to produce them.

iv. Differences in Wage Rates Between Countries and Occupations as Still Further Factors

In the case of foreign trade, Ricardo departs even

further from a view of the relative quantity of labor as the only determinant of relative value. He says, flatly: "The same rule which regulates the relative value of commodities in one country does not regulate the relative value the commodities exchanged between two or more countries."¹¹¹

The kind of problem that emerges for a strict labor theory of value in connection with foreign trade is that, with due allowance for costs of transportation, the same commodity tends, as we have seen, to have the same price throughout the world.¹¹² This is so, irrespective of the quantity of labor that must be employed to produce the commodity in different countries. For example, the price of a bushel of wheat is, let us say, three dollars. This is the price both to farmers in India and to farmers in the United States, even though the relatively backward methods of production in India may mean that it takes fifty or a hundred times the labor to produce a bushel of wheat in India than it does in the United States.

This case suggests yet another element entering into the determination of relative prices—namely, *relative wage rates*. The cost of production of wheat in India and the United States can be equal despite the fifty- or hundred-to-one difference in the quantity of labor required to produce wheat in the two countries, if wage rates in the United States are that much higher than in India.¹¹³ Furthermore, the inequality of wage rates for different grades of labor, such as skilled versus unskilled labor, leads products produced with the same quantity of labor in the *same country* to have different costs of production and thus different prices. For example, the watches produced with a thousand hours of skilled watchmakers' labor are far more costly than the quantity of cotton or wheat produced with a thousand hours of the labor of farm hands.

Ricardo himself did not recognize the role of relative wage rates in determining relative costs and relative prices within a given country. But his disciple John Stuart Mill clearly did. The latter wrote:

... if wages are higher in one employment than another, or if they rise and [*sic*] fall permanently in one employment without doing so in others, these inequalities do really operate upon values. . . . When the wages of an employment permanently exceed the average rate, the value of the thing produced will, in the same degree, exceed the standard determined by mere quantity of labour. Things, for example, which are made by skilled labour, exchange for the produce of a much greater quantity of unskilled labour; for no reason but because the labour is more highly paid.¹¹⁴

It should be realized, of course, that differences in wage rates are not a fundamental explanation of differences in the value of products, for they themselves ultimately rest on the comparative valuations made by the consumers of the various products produced with the

different kinds of labor.¹¹⁵

Furthermore, it should also be realized that just as there are differences in the quantity of labor required to produce the same good among different countries, so there are also differences in the quantity of labor required to produce the same good within any given country. This is the case insofar as economic progress takes place in a country. The effect of economic progress is that the portions of the supply of a commodity produced with the more recently adopted methods of production tend to be produced with less labor per unit than the portions of the supply that are produced with older methods of production. In such conditions, the competition of the newer, more efficient methods of production tends to reduce the price of the commodity to a point where it corresponds to less than the quantity of labor required to produce it under the older methods. At the same time, because the newer methods are as yet only partially adopted, the price of the product tends to correspond to more than the quantity of labor required to produce it under the newer methods. In such cases, the price of the commodity can be described as gravitating downward, toward correspondence with the quantity of labor required to produce it under the newest, most efficient method of production, as the use of that method becomes more and more widespread. But under conditions of continuous economic progress, the price will never actually reach that point, because before any one method of production can be fully adopted, still more efficient methods of production come to be adopted.

In cases of the kind just described, the effect is inequalities in the rate of profit among different producers of the same product. Those who produce with the more recent methods of production earn above-average rates of profit, while those who produce with the older methods of production earn below-average rates of profit or suffer outright losses. However, it is also a common occurrence for products to be produced with different quantities of labor in the same country because of differences in the degree of skill among wage earners within the same occupation. For example, in many occupations there are some workers who are capable of producing twice as much as other workers even though both work with the same kind of machinery and tools. In cases of this kind, the departure of the price of the product from the quantity of labor required to produce it will be compensated for by inequalities in wage rates. Just as in the case of inequalities in the productivity of labor between countries, the workers who are twice as efficient in a given occupation in a given country will tend to be paid double the wage rates of the less efficient workers. As in the case of foreign trade, the price of the product will correspond to labor cost, but not to labor quantity.

The Actual Significance of Quantity of Labor in Classical Economics

Thus, in the hands of the classical economists, the labor theory of value was a theory which held that the relative quantity of labor required in the production of goods was usually, but not always, the major determinant of their relative prices. A variety of other factors was recognized as operating alongside of relative quantity of labor as determinants of relative prices. And in some circumstances the relative quantity of labor was held not to be a determinant at all. When the classical economists' ideas on the determination of prices are all put together, it works out that in order for the quantity of labor required in production to be the *sole* determinant of the prices in whose formation it plays a role, a whole series of very special assumptions would have to be realized.

First, the tendency toward a uniform rate of profit on capital invested, which was discussed earlier in this book, would not only have to realize itself in the achievement of an actual uniform rate of profit in all branches of production, but also it would have to operate in conditions in which every branch of industry had the same ratio of capital invested to sales revenues, i.e., the same capital turnover ratio.¹¹⁶ On these two assumptions, the uniformity-of-profit principle would imply uniform *profit margins*. That is, there would not only be a uniform rate of profit on capital invested, but also a uniform ratio of profit to *sales revenues* in every branch of production. This is because if capital invested were everywhere in the same ratio to sales revenues, then profits would have to be a uniform percentage of sales revenues in order to be a uniform percentage of capital invested. Uniform profit margins, in turn, would imply a uniform relationship between prices and costs of production everywhere. Everywhere prices would stand in the same ratio to costs of production—for example, if the uniform profit margin were 10 percent, then everywhere prices would stand in the ratio of 100 to 90 in relation to costs of production.

If the further special assumption were realized that in every branch of production the costs of production broke down in the same proportion between labor costs and costs on account of materials and machinery (and any other items purchased from other business firms), then a uniform relationship between prices and costs of production would imply a uniform relationship between prices and a *series of prior wage payments*. For example, if everywhere half the cost were for wages and half for materials and machinery, etc., then a price of 100 for a consumers' good would correspond to 45 of wage payments in the direct production of the consumers' good, plus an additional 20.25 of wage payments in the production of the 45 worth of capital goods used in the production of the consumers' good, plus a further 9.1125 of

wage payments in the production of the 20.25 worth of capital goods used to produce those capital goods, and so on. (Forty-five is half of 90 percent of the 100 value of the consumers' good; 20.25 is half of 90 percent of 45; 9.1125 is half of 90 percent of 20.25.) The price of every good, in other words, would correspond to a uniformly diminishing series of prior wage payments. It would equal the sum of those prior wage payments each multiplied by the rate of profit, stated as a percentage of cost, compounded for the number of years by which the particular stage was removed from the sale of the ultimate consumers' good.

If, finally, the still further assumption were realized that there is only one uniform grade of labor in terms of skill and efficiency, with one uniform wage rate, then it would follow that product prices would everywhere tend to be proportional to the quantity of labor required to produce the various goods. For then, wage costs would always be in the same proportion to the quantity of labor purchased. With a uniform wage rate, a wage payment of 10, for example, represents the purchase of twice the quantity of labor as a wage payment of 5. In these circumstances, prices would be proportional to costs, to wage costs specifically, and to the quantities of labor purchased by the wage payments that underlie the wage costs.

Any deviation from any of these assumptions upsets any strict correspondence between price and quantity of labor, even in the cases in which quantity of labor does play an actual role in price determination. And this, I believe, is the real nature of the relationship between prices and the quantity of labor developed by the classical economists.

5. The "Iron Law of Wages" of Classical Economics

The shortcoming of the classical economists' theory of value was not their recognition of the very important role played by the quantity of labor required in production. It was, to a great extent, their failure to understand the role of marginal utility and consumer demand in determining the relative wage rates of different grades of labor and the relative prices of various other factors of production whose supply cannot be varied in immediate response to changes in demand.¹¹⁷

Much more serious, by far, was their failure clearly to understand that in a free and rational society wage rates have absolutely no tendency to conform to the cost of "subsistence" or to the quantity of labor required to produce "subsistence." This alleged connection—the so-called "iron law of wages"—was believed by the classical economists to exist mainly on the basis of a combination of the law of diminishing returns and the ideas they accepted from Malthus on population growth.

Diminishing Returns and the Malthusian Influence

As already explained in the discussion of the Ricardian theory of land rent, the classical economists often expressed the belief that if wages rose above the subsistence level, the effect would be an increase in population and thus the need to resort to land of inferior quality and to cultivate land already under cultivation more intensively, in order to provide food for the additional population.¹¹⁸ The consequence of this would be a diminution in the size of the product attributable to the performance of additional labor, or, as most contemporary economists would describe it, a fall in the marginal productivity of labor. This, in turn, would raise the cost of necessities to the workers and ultimately make it impossible for them to purchase anything but the bare minimum of necessities. At that point, population would stop growing because of the sheer economic inability of the average pair of parents to raise more than two children to adulthood.

In this way, subsistence was seen as marking the *equilibrium* level of real wages. When real wages were above subsistence, population grew, and then diminishing returns reduced real wages toward the subsistence level. If real wages fell below the subsistence level, people died of starvation, population fell, the poorest lands were thrown out of cultivation, and the remaining lands were cultivated less intensively. The result was that returns to labor increased, the price of necessities fell, and real wages moved up toward the subsistence level. In the words of Ricardo:

The natural [viz., equilibrium] price of labour is that price which is necessary to enable the labourers, one with another, to subsist and to perpetuate their race, without either increase or diminution.¹¹⁹

The market price of labour is the price which is really paid for it, from the natural proportion of the supply to the demand; labour is dear when it is scarce and cheap when it is plentiful. However much the market price of labour may deviate from its natural price, it has, like commodities, a tendency to conform to it.

It is when the market price of labour exceeds its natural price, that the condition of the labourer is flourishing and happy, that he has it in his power to command a greater proportion of the necessaries and enjoyments of life, and therefore to rear a healthy and numerous family. When, however, by the encouragement which high wages give to the increase of population, the number of labourers is increased, wages again fall to their natural price, and indeed from a re-action sometimes fall below it.

When the market price of labour is below its natural price, the condition of the labourers is most wretched: then poverty deprives them of those comforts which custom renders absolute necessities. It is only after their privations have reduced their number, or the demand for labour has increased, that the market price of labour will rise to its

natural price, and that the labourer will have the moderate comforts which the natural rate of wages will afford.¹²⁰

For the most part, Ricardo's statements in these passages are actually unobjectionable, given the conditions of a precapitalist society. In such primitive conditions, the connection he makes between wages and minimum subsistence is entirely consistent with the laws of supply and demand.

What is objectionable is such statements as: "With the progress of society . . . one of the principal commodities [food] . . . has a tendency to become dearer from the greater difficulty of producing it."¹²¹ If true, it would mean that food could be produced most easily by our caveman ancestors and has been becoming progressively more difficult to produce ever since. Obviously, the opposite is true.

Ricardo's Reservations

Although he clearly endorses the principle that wages have a tendency to conform to their "natural" rate, it is equally clear that Ricardo had some serious reservations. For just a few paragraphs later, he writes:

Notwithstanding the tendency of wages to conform to their natural rate, their market rate may, in an improving society, for an indefinite period, be constantly above it; for no sooner may the impulse which an increased capital gives to a new demand for labour be obeyed, than another increase of capital may produce the same effect; and thus, if the increase of capital be gradual and constant, the demand for labour may give a continued stimulus to an increase of people.¹²²

Furthermore, it turns out that subsistence, in Ricardo's view, does not really mean subsistence at all. It means rather that level of real wages above which the average working family is willing to bring up more than two children, and below which it is willing to bring up less than two children. "Subsistence," in other words, turns out to mean whatever level of real wages results in an equilibrium working population and thus in no tendency of real wages to fall because of population increase or rise because of population decrease. In Ricardo's words:

It is not to be understood that the natural price of labour, estimated even in food and necessaries, is absolutely fixed and constant. It varies at different times in the same country, and very materially differs in different countries. It essentially depends on the habits and customs of the people. An English labourer would consider his wages under their natural rate, and too scanty to support a family, if they enabled him to purchase no other food than potatoes, and to live in no better habitation than a mud cabin; yet these moderate demands of nature are often deemed sufficient in countries where "man's life is cheap" and his wants easily satisfied. Many of the conveniences now enjoyed in an English cottage would have been thought luxuries at an earlier period of our history.¹²³

And, further, along the same lines:

The friends of humanity cannot but wish that in all countries the labouring classes should have a taste for comforts and enjoyments, and that they should be stimulated by all legal means in their exertions to procure them. There cannot be a better security against a superabundant population.¹²⁴

In these two passages Ricardo's usage of the concept of "subsistence" is actually compatible even with describing the standard of living of the average worker *in the present-day United States* as subsistence. This would be the case if, with a fall in real wage rates below the present level, the average present-day American working family would decide to reduce the number of children it had to a point below the level necessary to keep up the present number of workers.

It should be realized that the observation of economic history from the perspective of the late eighteenth and early nineteenth centuries strongly supported the belief that the equilibrium level of real wages is subsistence—subsistence in the full-bodied sense of extreme poverty characterized by chronic hunger and malnutrition. This was because, again and again, the operation of the law of diminishing returns, coupled with population growth, had in fact brought wages down to actual minimum subsistence whenever, for a brief time, they had gotten above it. Prior to the nineteenth century, history had not yet provided any actual examples of the standard of living of the great mass of workers rising very far above the level of minimum physical subsistence and remaining there for very long. The Industrial Revolution was as yet too young. It was simply too soon for observers such as Ricardo to realize that the progress they were observing around them represented a radical break with all of previous human history.¹²⁵

Adam Smith's Mistaken Belief in the Arbitrary Power of Employers Over Wage Rates

A further element in the writings of the classical economists, on the basis of which they propounded the "iron law of wages," was their belief that employers possess arbitrary power over wage rates. Adam Smith believed that wages are the outcome of an unequal struggle between wage earners and employers, in which employers possess the allegedly decisive advantage of being able to hold out for a longer period of time. He writes:

What are the common wages of labour, depends every where upon the contract usually made between those two parties, whose interests are by no means the same. The workmen desire to get as much, the masters to give as little as possible. The former are disposed to combine in order to raise, the latter in order to lower the wages of labour.

It is not, however, difficult to foresee which of the two parties must, upon all ordinary occasions, have the advantage in the dispute, and force the other into a compliance

with their terms. The masters, being fewer in number, can combine much more easily; and the law, besides, authorises, or at least does not prohibit their combinations, while it prohibits those of the workmen. We have no acts of parliament against combining to lower the price of work; but many against combining to raise it. In all such disputes the masters can hold out much longer. A landlord, a farmer, a master manufacturer, or merchant, though they did not employ a single workman, could generally live a year or two upon the stocks which they have already acquired. Many workmen could not subsist a week, few could subsist a month, and scarce any a year without employment. In the long-run the workman may be as necessary to his master as his master is to him, but the necessity is not so immediate.¹²⁶

The apparent result of this alleged state of affairs, according to Smith, is that employers are in a position arbitrarily to drive wages as low as they like short of the point of depriving themselves of a supply of workers—i.e., to the level of minimum physical subsistence. In Smith's words:

But though in disputes with their workmen, masters must generally have the advantage, there is however a certain rate below which it seems impossible to reduce, for any considerable time, the ordinary wages even of the lowest species of labor.

A man must always live by his work, and his wages must at least be sufficient to maintain him. They must even upon most occasions be somewhat more; otherwise it would be impossible for him to bring up a family, and the race of such workmen could not last beyond the first generation.¹²⁷

In fairness to Adam Smith, it should be pointed out that on the very next page of *The Wealth of Nations*, he comes close to grasping the actual principle on which wages are determined in a free market—namely, the competition of employers for labor that is always inherently scarce—but he regards the case as atypical.

There are certain circumstances, however, which sometimes give the labourers an advantage, and enable them to raise their wages considerably above this rate [subsistence]; evidently the lowest which is consistent with common humanity.

When in any country the demand for those who live by wages; labourers, journeymen, servants of every kind, is continually increasing; when every year furnishes employment for a greater number than had been employed the year before, the workmen have no occasion to combine in order to raise their wages. The scarcity of hands occasions a competition among masters, who bid against one another, in order to get workmen, and thus voluntarily break through the natural combination of masters not to raise wages.¹²⁸

What Adam Smith says about the conditions of an increasing demand for labor applies in principle equally to conditions of a constant or even falling demand for labor. Even in the face of such a demand for labor, the quantity of labor demanded will exceed the supply of labor available if wage rates are sufficiently low. At that

point the scarcity of labor is once again felt, and the result is a competition of employers for labor. Moreover, as will be shown in Chapter 13, any fall in wage rates necessary to achieve full employment, is the cause of lower costs and more production, both of which operate to reduce prices and thereby to prevent the fall in wage rates from entailing a fall in the average worker's actual standard of living.¹²⁹

Ricardo's Confusions Concerning the "Iron Law of Wages"

In contrast to Adam Smith, who held that employers have arbitrary power over wages, Ricardo comes to the opposite mistaken conclusion, namely, that arbitrary power over wage rates resides with *the wage earners*. They allegedly have the ability to make employers grant wages above the level corresponding to the state of supply and demand for labor, and in so doing to reduce the rate of profit.

Consistent with this, nowhere does Ricardo present high profits as being made on the basis of subsistence wages. On the contrary, in Ricardo's view, when wages reach subsistence, profits *fall*, as the consequence of an effort to offset the fall in the wage earner's standard of living. What drives wages to subsistence, according to Ricardo, is not the arbitrary payment of low wages by employers, but, as we have seen, the rise in the price of food and other necessities caused by population growth and the operation of the law of diminishing returns. At that point, according to Ricardo, wages must be increased, to keep pace with the higher price of necessities, and this rise in wages reduces profits.

Ricardo claims that this rise in wages occurs apart from the operation of the supply and demand for labor:

Independently of the variations in the value of money, which necessarily affect money wages, but which we have here supposed to have no operation, as we have considered money to be uniformly of the same value, it appears then that wages are subject to a rise or fall from two causes:

1st. The supply and demand of labourers.

2dly. The price of the commodities on which the wages of labour are expended.¹³⁰

A few pages later, proceeding as though he has somehow established this alleged second cause, he reminds his readers that in addition to being regulated by supply and demand:

. . . we must not forget, that wages are also regulated by the prices of the commodities on which they are expended.

As population increases, these necessities will be constantly rising in price, because more labour will be necessary to produce them. If, then, the money wages of labor should fall [as the result of rising population and thus a

larger supply of labor], whilst every commodity on which the wages of labour were expended rose, the labourer would be doubly affected, and would be soon totally deprived of subsistence. Instead, therefore, of the money wages of labour falling, they would rise . . .¹³¹

The fact that the ultimate power over wage rates in Ricardo's view rests with the wage earners becomes clear in the following passages, in which he attempts to defend his position that a rise in the price of necessities must result in a rise in wages:

It may be said that I have taken it for granted that money wages would rise with a rise in the price of raw produce, but that this is by no means a necessary consequence, as the labourer may be contented with fewer enjoyments. It is true that the wages of labour may previously have been at a high level, and that they may bear some reduction. If so, the fall of profits will be checked; but it is impossible to conceive that the money price of wages should fall or remain stationary with a gradually increasing price of necessities; and therefore it may be taken for granted that, under ordinary circumstances, no permanent rise takes place in the price of necessities without occasioning, or having been preceded by, a rise in wages.

The effects produced on profits would have been the same, or nearly the same, if there had been any rise in the price of those other necessities, besides food, on which the wages of labour are expended. *The necessity which the labourer would be under of paying an increased price for such necessities would oblige him to demand more wages; and whatever increases wages necessarily reduces profits.*¹³²

Thus, in the last analysis, according to Ricardo, wages rise because the wage earners need higher wages in order to keep pace with the rise in the price of necessities.

Now this doctrine of wages rising to offset the alleged rise in the price of necessities is, of course, entirely wrong. It appears to be the result of nothing more than a desire on Ricardo's part to soften the harshness of the fact that his analysis ties real wage rates to subsistence by way of the operation of population changes and the law of diminishing returns.¹³³ According to that analysis, the only way that wages can recover to subsistence when conditions drive them below it is "after their [the wage earners'] privations have reduced their number." Only then, will "the market price of labour . . . rise to its natural price." The mechanism would be the operation of the law of diminishing returns in reverse, as the population and thus the supply of labor diminished because of such horrible events as famines and plagues. Instead of accepting his own analysis, Ricardo postulates a rise in wage rates to alleviate the wage earners' suffering without any reduction in the supply of labor.

Furthermore, it is actually inconceivable for any price (or wage) to rise without either the demand rising or the supply falling.¹³⁴ Inasmuch as Ricardo's context here, is

an alleged rise in wages without a fall in the supply of labor, it is necessary to conclude that at least implicitly he assumes that when wages fall to the subsistence level, there will somehow be an increase in the demand for labor that will be responsible for raising wage rates in the face of higher prices of necessities.

Ricardo's apparent belief in a kind of *deus ex machina* of a rising demand for labor to raise wage rates in the face of rising prices of necessities, is what leads him to the conclusion that there is a tendency toward a falling rate of profit, which, fortunately, is interrupted by improvements in the production of necessities.

The natural tendency of profits then is to fall; for, in the progress of society and wealth, the additional quantity of food required is obtained by the sacrifice of more and more labour. This tendency, this gravitation as it were of profits, is happily checked at repeated intervals by the improvements in machinery connected with the production of necessities, as well as by discoveries in the science of agriculture, which enable us to relinquish a portion of labour before required, and therefore to lower the price of the prime necessary of the labourer.¹³⁵

Ricardo expresses essentially the same thought in connection with foreign trade, but with more obvious radical connotations:

It has been my endeavour to show throughout this work that the rate of profits can never be increased but by a fall in wages, and that there can be no permanent fall of wages but in consequence of a fall of the necessities on which wages are expended. If, therefore, by the extension of foreign trade, or by improvements in machinery, the food and necessities of the labourer can be brought to market at a reduced price, profits will rise. If, instead of growing our own corn, or manufacturing the clothing and other necessities of the labourer, we discover a new market from which we can supply ourselves with these commodities at a cheaper price, wages will fall and profits rise; but if the commodities obtained at a cheaper rate, by the extension of foreign commerce, or by the improvement of machinery, be exclusively the commodities consumed by the rich, no alteration will take place in the rate of profits. The rate of wages would not be affected, although wine, velvets, silks, and other expensive commodities should fall 50 per cent., and consequently profits would continue unaltered.¹³⁶

This last paragraph appears to suggest the Marxian notion that improvements in production simply pass the wage earners by, because they are followed by a corresponding reduction in wages. It is possible to argue for this interpretation on the basis of other passages in Ricardo as well.

Nevertheless, while this interpretation is logically consistent with much of what Ricardo says, it is not his actual meaning. His actual meaning is that the fall in wages here should be understood as a limited one, eliminating an extraordinary increase in wages to compensate

for the rise in the price of necessities beyond the point of minimum subsistence. Once this limited fall in wages takes place, the effect of further improvements in production *is to raise real wages through the mechanism of falling prices unaccompanied by any further fall in money wages*. His actual meaning is essentially the same as the doctrine developed in Chapter 14 of this book under the name "The Productivity Theory of Wages." Support for this interpretation appears on the very next page following the passage last quoted. Here it is pointed out how improvements in production generally do not operate to raise the rate of profit, but to reduce prices and thereby to benefit *all classes*.

The remarks which have been made respecting foreign trade apply equally to home trade. The [economy-wide, average] rate of profits is never increased by a better distribution of labour, by the invention of machinery, by the establishment of roads and canals, or by any means of abridging labour either in the manufacture or in the conveyance of goods. These are causes which operate on price, and never fail to be highly beneficial to consumers; since they enable them, with the same labour, or with the value of the produce of the same labour, to obtain in exchange a greater quantity of the commodity to which the improvement is applied; but they have no effect whatever on profit. On the other hand, every diminution in the wages of labour raises profits, but produces no effect on the [average] price of commodities. One is *advantageous to all classes, for all classes are consumers*; the other is beneficial only to producers; they gain more, but everything remains at its former price. In the first case they get the same as before; but everything on which their gains are expended is diminished in exchangeable value.¹³⁷

The Actual Meaning Ricardo Attached to "A Fall in Wages"

Indeed, the kind of fall in wages and rise in profits Ricardo usually has in mind turns out *not* to mean a fall in the wage earner's standard of living—in fact, it is fully compatible with a *rise* in the wage earner's standard of living. The most formidable evidence for this view occurs in Section 7 of his chapter "On Value." There he makes it clear that he is talking of changes in wages and profits in the conditions of a monetary unit of invariable "inner" value, that is, a monetary unit such that all variations in prices are the result of changes on the side of production and supply, not changes on the side of money and demand.

Ricardo's theoretical stand-in for such a monetary unit is a fixed aggregate quantity of labor employed in the production of commodities. However, his conclusions can be understood just as well, and far more easily, on the assumption of a fixed aggregate monetary demand—viz., expenditure—for the output of the economic system. (A fixed volume of spending for output would

represent a monetary unit of invariable “inner” value, in that all changes in prices would reflect only changes on the side of output—that is, production and supply—not changes on the side of money and spending. This is because with the amount of monetary demand—spending—being the same, the only way that prices could rise would be by virtue of a fall in output, and the only way that prices could fall would be by virtue of a rise in output. All changes in prices would thus proceed from the side of output, not from the side of money. Money would be of invariable inner value in the sense that even though prices changed and thus the value of money changed, the changes took place from the side of output, not from the side of money.¹³⁸) He states:

It is not by the absolute quantity of produce obtained by either class, that we can correctly judge of the rate of profit, rent, and wages, but by the quantity of labour required to obtain that produce. By improvements in machinery and agriculture the whole produce may be doubled; but if wages, rent, and profit be also doubled, these three will bear the same proportions to one another as before, and neither could be said to have relatively varied. [To understand this point, imagine that the money value of the aggregate product of the economic system is constant at 1,000 monetary units, which is the total of the spending to buy it. Now imagine that production and the supply of goods sold double and thus that prices halve. If wages, rent, and profits all continue at the same respective monetary magnitudes as before, then, in Ricardo’s view none of them has changed, even though the buying power of each of them has doubled.] But if wages partook not of the whole of this increase; if they, instead of being doubled, were only increased one-half; if rent, instead of being doubled, were only increased three-fourths, and the remaining increase went to profit, it would, I apprehend, be correct for me to say that rent and wages had fallen while profits had risen; for if we had an invariable standard by which to measure the value of this produce we should find that a less value had fallen to the class of labourers and landlords, and a greater to the class of capitalists than had been given before. We might find, for example, that though the absolute quantity of commodities had been doubled, they were the produce of precisely the former quantity of labour. Of every hundred hats, coats, and quarters of corn produced, if

The labourers had before 25
 The landlords 25
 And the capitalists 50
 100:

And if, after these commodities were double the quantity, of every 100

The labourers had only 22
 The landlords 22
 And the capitalists 56
 100:

In that case I should say that wages and rent had fallen and profits risen; though in consequence of the abundance of

commodities the quantity paid to the labourer and landlord would have increased in the proportion of 25 to 44. Wages are to be estimated by their real value, viz., by the quantity of labour and capital employed in producing them, and not by their nominal value either in coats, hats, money, or corn. Under the circumstances I have just supposed, commodities would have fallen to half their former value, and if money had not varied, to half their former price also. If then in this medium, which had not varied in value, the wages of the labourer should be found to have fallen, it will not the less be a real fall because they might furnish him with a greater quantity of cheap commodities than his former wages.¹³⁹

What Ricardo means to say in the passages just quoted is that production doubles and prices halve. With total money income constant at 1,000 units of money, aggregate wages and aggregate rents fall from 250 each to 220 each, while aggregate profits rise from 500 to 560. Even though the 220 each of wages and rent now buy as much as 440 would have bought initially, wages and rent still fall in terms of an invariable money. Their fall in terms of such a monetary unit will not be any the less an actual monetary fall because they enable the wage earner and landlord to buy a greater quantity of the less expensive commodities than did their former wages and rents.

What must be stressed is that while this is certainly a fall in wages in Ricardo’s meaning of the term, it has nothing whatever to do with an approach of wages to subsistence. What contemporary economists would call real wages sharply increase in this case. (What Ricardo means by real wages, in contrast, is total money wages in the conditions of an invariable money. And he regards the goods the wage earners can actually buy as merely being nominal wages.)

Hopefully, it is now clear that Ricardo does not in fact argue that the capitalists arbitrarily set wages at the level of minimum subsistence, and that, indeed, the core of his analysis is actually fully compatible with real wages steadily rising and doing so *precisely on the basis of the activities of the capitalists*, whose savings create the demand for labor and capital goods and who are responsible for the steady rise in the productivity of labor and thus for a steady fall in prices relative to wages. Hopefully, it is also clear that in the writings of Ricardo, if and when wages do fall to subsistence, not only is the cause held to be the combination of population growth and the operation of the law of diminishing returns rather than any greed on the part of employers for higher profits, but also the effect is held to be a *reduction* in the rate of profit, not an increase.¹⁴⁰ Profits, according to Ricardo, are definitely not the result of any arbitrary imposition of subsistence wages, which is what Marx alleges them to be.¹⁴¹

Classical Economics' Mistaken Denial of the Ability to Tax Wage Earners

However inconsistently, insofar as the classical economists believed that the equilibrium level of real wages was minimum subsistence, they were led to the conclusion that wage earners cannot be made to pay a significant amount of taxes. After all, if wages are merely equal to subsistence, what is there to tax? Thus, for example, Ricardo writes: "Dr. [Adam] Smith uniformly, and I think justly, contends, that the labouring classes cannot materially contribute to the burdens of the State. A tax on necessaries, or on wages, will therefore be shifted from the poor to the rich . . ."142

This view is entirely false. We saw in Chapter 9 that taxes on the "rich"—on businessmen and capitalists—are overwhelming borne by the wage earners in the form of a lower demand for labor and a lower productivity of labor, which latter is caused by a lower demand for capital goods relative to consumers' goods and reduced incentives to improve production.¹⁴³ The truth is that wage earners always end up bearing the major burden of taxes; they bear the burden whether the taxes are levied on them directly or on businessmen and capitalists.

The truth of this proposition does not depend on real wages initially being above subsistence, as happens to be the case today, when they exceed subsistence many times over. If, as in most of history and in most countries even now, real wages are at the level of subsistence, an increase in taxes in any form operates to reduce them below subsistence. It does so either by directly reducing the wage earners' spendable income, if it takes the form of an additional income tax they must pay, or the buying power of their incomes, if it is an additional sales tax they must pay. If it is an additional tax on the "rich," it reduces the demand for labor and thus the wage earners' pretax incomes; it also reduces the supply of goods produced and available for them to buy, and thus raises the prices they must pay. The wage earners simply cannot escape the burden of the tax.

If real wages are initially at the subsistence level, the effect of any tax increase is that wage earners are literally taxed to death. Wages then recover to the subsistence level from a point below the subsistence level insofar as a reduced population makes it possible to produce agricultural commodities and minerals under conditions of a higher productivity of labor. At that point, the higher productivity of labor resulting from the depopulation offsets the burden of the tax.

If a modern, division-of-labor economy should ever be driven to the point of subsistence wages, and then taxes be further increased, real wages would not recover as the result of depopulation. The depopulation would further reduce the productivity of labor, by reducing the

extent of the division of labor. A collapse of society would ensue.

6. Marxian Distortions of Classical Economics; The Final Demolition of the Exploitation Theory

In the last two sections of this chapter, I have shown the actual nature of classical economics insofar as it is alleged to underlie the Marxian exploitation theory. Indeed, precisely on the foundation of classical economics, I have demolished the conceptual framework of the exploitation theory. I have shown how the labor theory of value of classical economics—at least as developed by Ricardo, who was the leading theorist of the school—stands merely as a partial principle, alongside of a variety of other principles of price determination, and can actually be used to express the essential productive contribution of businessmen and capitalists to the rise in real wages by virtue of continuously raising the productivity of labor and thereby making goods more and more abundant relative to labor. I have shown that in the hands of Ricardo even the so-called iron law of wages of classical economics does not actually lend very much support to the exploitation theory. Thus, the notion that classical economics implies Marxism is at best highly superficial. In essentials, the opposite is true, as my critique of the conceptual framework of the exploitation theory on the basis of classical economics should make clear.

In Chapter 14, I will explain in detail Marx's very different version of the labor theory of value and "iron law of wages." A reading of that material, in the light of the account of the classical economists' views that has been presented in this chapter, will make it obvious that Marx's views represent gross distortions of the classical economists' ideas on these subjects.

Chapter 14 will complete the vital work of refuting all remaining aspects of the exploitation theory. It will provide a systematic critique of the Marxian version of the iron law of wages—that is, the notion that employers have the power arbitrarily to set wage rates at minimum subsistence. It will hunt down the numerous manifestations of this doctrine in the prevailing political-economic ideology of the twentieth century and one by one subject them to a thoroughgoing critical analysis, from which they will be unable to recover in the mind of any rational reader who takes the trouble to study and understand the analysis.

Chapter 14 will follow an extensive explanation of the nature of aggregate demand, in chapters expounding the quantity theory of money, Say's law of markets, and the cause and remedy for mass unemployment. Following this necessary preparatory work (which, of course, is enormously valuable in its own right), the critique of the

Marxian version of the iron law of wages will be provided primarily in the form of the presentation of a totally different, positive theory of wages—one that is fully

compatible with the essential doctrines of classical economics. This theory of wages, I call, by the title of Chapter 14, *The Productivity Theory of Wages*.

Notes

1. The productive role of commodity speculation and the commodity markets has already been explained. See above, pp. 191–192.
2. Most of the material that explains these matters in the next three sections originally appeared in my article “Definitions Pertaining to Production and Consumption,” *Il Politico* 32, no. 1 (March 1967).
3. In today’s environment of blatant irrationalism and open hostility to science and technology, it must be stressed that *proof* of inherent destructiveness must be shown before an activity is to be disallowed the title of productive. There is no such proof to disqualify even alcohol, tobacco (in forms other than cigarettes), and gambling, when resorted to in moderation. Still less is there any reason to challenge the productivity of the manufacture and sale of such substances as coffee, saccharin, red meat, white flour, white bread, sugar, cow’s milk, table salt, and so on, the claims of assorted cultists and food faddists to the contrary notwithstanding.
4. Cf. James Mill, *Commerce Defended* (London, 1808); reprinted in *Selected Economic Writings of James Mill*, ed. Donald Winch (Chicago: University of Chicago Press, 1966) p. 128.
5. The meaning of the terms productive, unproductive, and reproductive consumption in the physical sense was explained above, on pp. 131–132.
6. These concepts appear in the writings of Adam Smith and his followers under the names “productive and unproductive labor.” Unfortunately, the classical economists were highly inconsistent in their use of these terms and frequently employed them to refer to a very different distinction, namely, the distinction between labor employed in the production of tangible, material goods and labor employed not in the production of tangible, material goods. (See below, the quotations from Adam Smith on p. 456.) Apart from this inconsistency, Adam Smith and James Mill can be acknowledged as the originators of the basic distinctions I have employed in this discussion. Cf. Adam Smith, *The Wealth of Nations* (London, 1776), bk. 2, chap. 3; reprint of Cannan ed. (Chicago: University of Chicago Press, 2 vols. in 1, 1976), 1:351–371. (Where appropriate, from now on, specific page references to the University of Chicago Press reprint will be supplied in brackets.) Cf. also James Mill, *Commerce Defended*, chaps. 5 and 6 (pp. 105–139) in *Selected Economic Writings of James Mill*.
7. In case anyone wonders about the classification of government employees engaged in tax collections or employees of private charities who are engaged in fund raising, see below, pp. 454–455.
8. See above, p. 132.
9. See above, *ibid.*
10. See above, p. 40.
11. On occasion, I will include accumulated savings in the

- methods I offer for measuring the degree of capital intensive-ness of the economic system. See below, for example, Chapter 14, n. 71.
12. John Kenneth Galbraith, *The Affluent Society*, 3d ed. (Boston: Houghton Mifflin, 1976), pp. 110–111.
13. It should go without saying that productive expenditures made for the purpose of reducing costs of production, such as many of those made by a company’s research and development department, are productive expenditures. They too are made for the purpose of bringing in sales revenues. Their only distinction is that they seek to do so with a greater profit than would otherwise be the case. All the expenditures made by business enterprises for business purposes are productive expenditures.
14. Subsequent discussion in the next section of this chapter, concerning the closely related doctrine of imputed income, will make still clearer the absurd results implied in the notion that a saving of expense is the equivalent of actually earning an income.

85. It is important to realize that large salaries and bonuses for key executives can be justified even in conditions of recession or depression, insofar as they are earned for sharply cutting costs, including laying off large numbers of unnecessary employees. As illustration of this principle, one should consider how desirable it would be for the U.S. Postal Service to become privately owned and for the new key executives to earn tens of millions of dollars in salaries and bonuses by virtue of massive firings of unnecessary or unproductive employees that would result in annual savings of hundreds of millions of dollars. Fortunately, this kind of process is what does occur in private business when necessary. Thus, the current complaints about the injustice of executives earning high incomes in the midst of layoffs likely are fundamentally unfounded.

PART THREE
THE PROCESS OF ECONOMIC PROGRESS

CHAPTER 12

MONEY AND SPENDING

1. The Quantity Theory of Money

The quantity theory of money holds that the volume of spending in the economic system, for goods, for labor, or any other broad economic category of things, is determined primarily by the quantity of money that exists in the economic system. To state the theory in the simplest possible terms: the amount of money that is *spent* is determined primarily by the amount of money that *exists*. The quantity theory of money can be expressed in terms of the following simple equation, which relates the quantity of money to aggregate demand in the sense of the volume of spending:

$$M \times V = D,$$

where M is the quantity of money in the economic system, D is the aggregate demand, as manifested in a definite total expenditure of money in the economic system, and V is the average number of times a unit of the money supply is spent in the period (i.e., the so-called velocity of circulation of money).

For example, as these words are written, the money supply in the United States is approximately \$1,150 billion. The so-called gross domestic product (GDP) (formerly gross national product or GNP), which is the most commonly used measure of aggregate spending, is approximately \$6,700 billion.¹ The implied average number of times a dollar is spent in a way that counts in GDP is thus approximately 5.8.

The money supply embraces all directly spendable money—all commonly used means of payment. In the

context of modern economic conditions, this includes paper currency, coin, and, quantitatively most important nowadays, checking-account balances (including balances transferable by telephone or computer). As of the end of 1993, the money supply of the United States amounted to \$329 billion of coin and currency, including \$8 billion of outstanding traveler's checks, and \$799 billion of checking account balances. The total money supply, therefore, amounted to \$1,128 billion.²

GDP currently consists almost 90 percent of consumption expenditures: \$4,585 billion reported as personal consumption expenditures, \$1,169 billion of government expenditures for goods and services, almost all of which is consumption, and a further substantial portion of the \$284 billion reported as investment in residential structures, but which in fact is consumption.³ Thus, out of a current GDP of approximately \$6,700 billion, well over \$5,700 billion represents one form or another of consumption expenditure.

Because it is comprised overwhelmingly of consumption spending, GDP can be taken as an approximate measure of aggregate *consumer* demand in the economic system. The velocity of circulation figure which relates GDP and the money supply could be termed GDP velocity or consumption velocity, since it reflects the number of times the average dollar of the money supply is spent in a way that counts in GDP, which essentially means: is spent for consumption. However, because of the virtual equivalence of GDP and consumption spending with national income, it happens that this measure of velocity is called income velocity.⁴ In any case, for the sake of

greater accuracy, the above formula relating the quantity of money and aggregate demand should be rewritten as

$$M \times V = D_C,$$

where D_C is the aggregate demand for consumers' goods, as manifested in a definite total expenditure of money to buy consumers' goods.

For many purposes, it is necessary to use a larger measure of total spending than GDP or consumption. Total aggregate demand for all products, consumers' goods or capital goods, is one such measure; that plus all wage payments (a concept I refer to as Gross National Revenue—GNR) is another; total spending of all kinds, including for stocks, bonds, and other securities, is yet a third.⁵ When these measures of aggregate demand are used, a correspondingly different figure for velocity of circulation results. The best known is called transactions velocity, which relates the quantity of money to the total of spending of every description.

The relationship between the quantity of money and the volume of spending in the economic system (whether that volume is conceived of relatively narrowly, as consisting merely of consumption spending, or more broadly) can begin to be understood by grasping the following simple and obvious connection between more money and more demand. Namely, an increase in the quantity of money raises demand because when the new and additional money comes into existence, its owners spend it. Those upon whom the new money is spent, in turn, respent it. The additional money is spent and respent over and over again, so long as it continues in existence. And in this way it raises the amount of spending that takes place in any given year.

It is probably easiest to visualize this process in the conditions of a gold standard, in which gold coins are money. Thus imagine that we are back in the old West, and some miners discover gold. They take their gold to the mint and have it manufactured into coins. Then they spend the coins in a frontier town. The merchants on whom they spend them turn around and subsequently respent them. And so it goes, with the new coins being spent and respent over and over and thus raising the aggregate demand of any given year.⁶

Nothing essential in the process is changed, except for the way that new and additional money comes into existence, if we substitute present-day paper currency and checkbook money for the gold coins of the old West. Thus, suppose that the U.S. Treasury is running short of money. It calls up its banker, the Federal Reserve System, and asks for a loan. The Federal Reserve receives some securities from the Treasury—bonds, Treasury bills, or whichever—and credits the Treasury's checking account with the proceeds of the loan. The Federal Reserve could

print currency for the Treasury and the Treasury could simply spend the currency. But under modern conditions the Treasury wants to make payments by check, not by currency. So the Federal Reserve credits the Treasury's checking account, and new and additional money has come into existence at the stroke of a pen (or the touch of a few computer keys).

Having received a credit to its account, the Treasury can now write additional checks. It sends out, let us assume, a batch of social security checks. The recipients of these checks take them to their banks. They can either cash them or deposit them in their own checking accounts. It does not matter which they do. If they cash them, the banks will have to take the checks to the Federal Reserve System and obtain currency for the checks. Then the situation from this point on is literally a matter of the printing of money. The currency the social security recipients get they will spend, and those on whom they spend it will respent it, and so on. New and additional paper currency will pass from hand to hand, just as in our earlier example new and additional gold coins passed from hand to hand.

But suppose the social security recipients deposit the checks in their checking accounts. In this case, they are in a position to write additional checks of their own and they now spend their social security payments in this way instead of spending currency. Those to whom they write checks in turn deposit the checks in their checking accounts, and subsequently write checks of their own. In this case, checking deposits pass from hand to hand instead of currency. In all essentials, the process is identical with the spending of currency.

Of course, at any time, the recipient of a check is free to cash it and obtain currency, just as the owner of currency is free to deposit it and write checks. The point is that money is created equally by the expansion of the currency or the checking deposits of the Federal Reserve System. It circulates equally in the form of the passage of currency or the passage of checking balances from hand to hand.

Unlike gold and silver, however, the paper and checkbook money of the government can be created virtually without limit and without cost. While gold and silver are rare in nature and typically require laborious mining operations in their supply, the quantity of paper and checkbook money is not limited even by the supply of paper—additional zeros can be printed on the same paper. The cost of printing any piece of paper money, whether a dollar bill or a hundred dollar bill, is only a fraction of a cent. The cost of crediting the Treasury's checking account with a billion dollars is not much greater. *As a result, there is nothing intrinsic to paper or checkbook money that operates to preserve its value.*

Paper and checkbook money can be created by the government in any quantity, for any purpose, for all practical purposes, effortlessly and costlessly. The power to create it constitutes an unlimited power to buy up the people's wealth and depreciate the value of money. I will show later on to what extent the government has already used this power. (From now on, incidentally, for the sake of brevity of expression, I will generally use the words "paper money" as standing both for currency and checkbook money.)

The Quantity Theory of Money as the Explanation of Rising Prices

The quantity theory of money explains the persistent rise in prices experienced in the United States and all other countries over the last two generations or more. In the simplest possible terms, the value of money, like the value of anything else, is determined by its quantity. The greater the quantity of any good, the lower is the value of that good. The greater the quantity of money, the lower is the value of money. A lower value of money, of course, means higher prices of goods.

The same thought can be expressed more precisely by means of our equation for aggregate demand. However, we must add to that equation the further equation for expressing the general consumer price level in terms of the relationship between the aggregate demand for consumers' goods and the aggregate supply of consumers' goods. The demand/supply equation states that

$$P = \frac{D_C}{S_C}$$

where P is the general level of consumers' goods prices, in the sense of the weighted average of the prices at which consumers' goods are actually sold, D_C , is the aggregate demand for consumers' goods, as manifested in a definite total expenditure of money to buy consumers' goods, and S_C is the aggregate supply of consumers' goods, as manifested in a definite total quantity of consumers' goods produced and sold.

As used in the above equation, and everywhere throughout this book, unless indicated otherwise, the term demand means the willingness combined with the ability to spend money, as manifested in the expenditure of a definite amount of money. Similarly, supply means the existence of goods combined with the willingness of their owners to sell them, as manifested in the sale of a definite quantity of goods.⁷

The above formula shows that the general consumer price level is merely *the arithmetical quotient of a numerator divided by a denominator. Demand is the numerator, and supply is the denominator.* It is important to learn to think of the price level in just these terms,

namely, as the arithmetical quotient of a numerator—demand—divided by a denominator—supply.

Let us use some concrete numbers in our formula, to make it more real. Thus, consider initially the price of a single good, say, the price at which packs of cigarettes are sold in a given supermarket in a given week. We want to know what is the average price at which packs of cigarettes in that supermarket were sold last week. To find the answer, we must divide the number of packs sold into the total expenditure to buy those packs, that is, the supply into the demand. If, for example, one thousand packs were sold for one thousand dollars, then the average price at which a pack was sold was one dollar. In exactly the same way, we could calculate the average price at which a pair of shoes was sold last week in a given shoe store, and similarly for any good in any period of time.

All we need do is realize that exactly the same principle applies to the general consumer price level in the sense of the weighted average of the prices at which consumers' goods are sold in the economic system as a whole. At this level of analysis, we must conceive of cigarettes, shoes, and all other goods as representing varying quantities of an abstract unit of goods in general and thus as capable of being added up into an aggregate supply. Whatever the concrete difficulties we might encounter in attempting to implement this concept, the basic idea is very clear and we repeatedly rely on it in our thinking. For example, no one has any doubt that the aggregate production and supply of consumers' goods in the United States today is far greater than it was a century or even a generation ago, or that it is far greater than the aggregate production and supply of consumers' goods in contemporary Great Britain, say.

Thus let us conceive of an economic system in which the total spending for consumers' goods during the year is a trillion (i.e., one thousand billion) dollars, and in which the abstract quantity of consumers' goods that is sold is one billion units. In this case, it is clear that the general consumer price level must be one thousand dollars per unit. It equals the division of the demand by the supply. The essential point to grasp here is that the general consumer price level reflects the exchange of some definite overall quantity of consumers' goods, in whatever units stated, against some definite overall expenditure of money to buy those consumers' goods. As I stated in Chapter 7, in any given year, some definite mass of consumers' goods—houses, cars, soap, matches, cigarettes, shoes, and everything else—exchanges against some definite overall expenditure of money. The mass of consumers' goods goes up against the total expenditure of money to buy them, and the result, the arithmetical quotient, is the general consumer price level.⁸

An expanding quantity of money operates to raise the general consumer price level by virtue of raising aggregate demand relative to aggregate supply. Aggregate demand rises while aggregate supply stays the same, or it rises more rapidly than aggregate supply. For example, while aggregate supply rises 2 percent in a year, aggregate demand rises by 6, 8, or 10 percent, with the result that the general consumer price level rises by 4, 6, or 8 percent in the year.

A system of *fiat paper money*, that is, a system in which the monetary unit is a mere piece of paper stamped as such by government officials—a system in which pieces of paper are not a claim to anything beyond themselves and thus themselves possess ultimate debt-paying power—such a system virtually guarantees that prices will rise. Under such a system, the increase in the quantity of money is limited only by the self-restraint of government officials. As will be shown, these officials have great incentives to increase the quantity of money and are under constant pressure to increase it. Hence, the quantity of money increases at a rate sufficient to increase aggregate demand more rapidly than aggregate supply, with the result that prices rise.

In contrast, it must be noted that under a system of *commodity money*, that is, for all practical purposes, a system in which the monetary unit is defined as a definite physical quantity of gold or silver, there is no inherent bias toward rising prices. The annual increase in the supply of gold and silver is always extremely limited because of the rarity of these metals in nature and the great cost of mining them. The greatest ingenuity of man has never been able to increase their supply very rapidly for very long. As a result, the use of a gold or silver money can never be accompanied by a sustained rapid rise in demand, or, therefore, in prices. Even when the New World was discovered and the accumulated treasure of the Aztecs and Incas was seized by Spain and added to the money supply of Europe, and many new discoveries of gold and silver were made, it took an entire century in most of the countries of Europe for prices to double or triple.

In normal circumstances, under a precious metals monetary system, the increase in the quantity of money is largely an accompaniment of the general increase in the ability to produce; it is the result of improvements in such fields as machinery, the means of transportation, and the sciences of engineering, metallurgy, and chemistry. Indeed, in normal circumstances a gold or silver money is accompanied by constant or even *falling* prices, because the limited increase in demand that larger supplies of gold and silver make possible tends to be offset, or more than offset, by equal or greater increases in the supply of other goods. The quantity of money grows, but

usually not at a more rapid pace than production in general, indeed, quite possibly at a slower pace. In the latter case, the general consumer price level falls. This last fact is well illustrated by the economic history of the United States: prices actually fell in almost every year in the generation preceding the discovery of the California gold fields in 1848, and again in the generation from 1873 to 1896.

2. The Origin and Evolution of Money and the Contemporary Monetary System

It is necessary to explain how the present monetary system of paper and checkbook money, and the government's unlimited power to create money, came into being, and, before that, how the precious metals came to be money, and, still earlier, how money of any kind originated.

Money evolved out of barter. What made it evolve was the actions of individuals in serving their self-interests. As explained in Chapter 5, in conditions of barter, exchanges are confined to situations in which a double coincidence of wants exists, that is, a situation in which each of two people holds opposite valuations with respect to goods they possess, with each valuing the good in the possession of the other more highly than the good that is in his own possession. For example, *A* who possesses a chocolate bar prefers the pack of cigarettes possessed by *B*, while *B* prefers *A*'s chocolate bar to his (*B*'s) pack of cigarettes. When, as was frequently the case, a double coincidence of wants was not present, no exchange could take place.⁹

Some of our more intelligent ancestors who encountered the problem of the lack of a double coincidence of wants invented the practice of *indirect exchange*, which others soon copied.¹⁰ What this means is that they exchanged the goods they possessed and wished to exchange, for other goods which they themselves did not desire but which the individuals whose goods they sought did desire.

For example, the owner of a boat who desired a team of horses owned by someone who did not desire a boat, exchanged the boat for goods that the owner of the horses did desire, or which people possessing such goods desired. Perhaps he would exchange his boat for an ox that the owner of the horses desired; perhaps he first had to exchange it for a quantity of iron or wheat or whatever before he could obtain the ox desired by the owner of the horses. (The complications of this example, incidentally, would be multiplied thousands of times over in the case of anyone who would attempt to live as a specialist in a barter economy. Such an individual would have to go through a comparable process of multiple exchanges in

order to obtain practically any good or service he desired, unless his own good happened to be the kind frequently sought by large numbers of people. As we have seen this is why significant division of labor is impossible in a barter economy.¹¹⁾

Thus, people began to exchange their goods for other goods which they sought neither as articles of personal consumption nor as means of further production, but as means of effecting further exchanges. In this way, *media of exchange* began to develop.

In this process, certain goods naturally come to be more widely preferred as media of exchange than others. Other things being equal, the larger the number of users of a good as an ordinary commodity and the more frequent their use of it, the more it would be preferred as a medium of exchange. For once in possession of such a good, the likelihood of finding someone who possessed what one desired and who was willing to accept this good would be substantially greater than the likelihood of finding someone who possessed what one desired and who was willing to take either one's original good or any other good.

It is on this principle that in societies of nomads, cattle emerge as a kind of money. Practically all nomads want more cattle, as the means of supporting larger families and larger numbers of servants. As a result, anyone who wants something from nomads is more likely to be able to obtain it if he can offer them cattle. It was on the same principle that in the years immediately following World War II, cigarettes emerged as a medium of exchange in the black markets of various European countries. The large number of people seeking cigarettes to smoke made cigarettes a logical good even for nonsmokers to seek in exchange for their goods. Once in possession of cigarettes, the likelihood of finding someone in possession of the goods one wanted was greatly increased.

The example of cigarettes contains a further principle. Namely, the process of certain goods being selected as media of exchange in preference to others tends to be self-reinforcing and cumulative. As soon as nonsmokers become willing to accept cigarettes, because of the large number of smokers to trade with, the effect is to increase the ability of cigarettes to serve as a medium of exchange, because now they are more widely acceptable than before. It is in this way that the acceptability of the most preferred medium or media of exchange tends to go on increasing, until it or they are universally acceptable—i.e., have developed into money. Money is merely a medium of exchange whose use has grown to the point where it is directly and readily exchangeable against all other goods in a given geographical area.

In different periods of history, in different places, a variety of goods have served as media of exchange.

Among them have been cattle, sheep, hides, furs, cocoa, tobacco, salt, sea shells, beads, iron, copper, and, of course, gold and silver. Everywhere, however, the rise of civilization was accompanied by the triumph of gold and silver over all other contenders for the office of money.

This was no accident. The rise of civilization entails fixed settlements, trade over great distances, and economic activity spanning long periods of time. Such developments make the use of animal or vegetable products as media of exchange unsuitable. Such things are all perishable and relatively expensive for dwellers in fixed settlements to transport or store. In comparison with them, practically any of the metals is superior because of its imperishability and lower costs of storage. The metals are also divisible and recombining, something that is totally impossible in the case of animals, sea shells, beads, and the like. The precious metals have the further decisive advantage of representing a comparatively high exchange value in a small bulk. As a result, it is less costly to transport or store a given amount of exchange value in the form of gold or silver than in the form of iron, copper, tin, or any other base metal.

Furthermore, in comparison with precious stones, the precious metals have the advantage of uniformity, in that each quantity of a definite purity is perfectly substitutable for any other equal quantity of the same purity. This makes it far easier to appraise pieces of precious metal. The ability to divide and recombine units of precious metal also enormously widens the market for any given quantity. These circumstances greatly reduce the difference between the retail price, at which one must buy, and the wholesale price, at which one must sell. In the case of precious metals, this difference is relatively insignificant. In the case of precious stones, it is very considerable.

Thus, the precious metals came to be money because they are the most suitable commodities for most people to save.¹²⁾ Their desirability as a means of saving—as a so-called store of value—made them acceptable to large numbers of people as a means of payment, namely, to those who wanted to save them. A process occurred in which for some time those who held part of their savings in gold or silver originally had to buy gold or silver with an earlier existing money, such as the iron coins of the early Roman Republic, and then, when they wished to use the gold or silver to make purchases, sell the gold or silver for the existing money. But as the number of people who wished to hold precious metals as a store of value reached a certain critical proportion of the population, individuals who possessed precious metals increasingly found that they could exchange them directly with other individuals who possessed the goods they desired and who, for their part, wished to add to their own gold or

silver holdings. The willingness of a significant number of people to accept the precious metals in exchange led others, who did not wish to hold the precious metals as a store of value, also to accept them in exchange—in the knowledge that they could reexchange them with those who did. This, of course, increased the acceptability of the precious metals as media of exchange and on that basis made them still more acceptable as media of exchange.

The holding of precious metals as a store of value and their growing use as media of exchange represented an additional demand for them over and above the demand for them as ordinary commodities. This additional demand could be met only with increasing difficulty, because of the comparative rarity of these metals in nature. The result was a rise in the value of the precious metals, which further reinforced their suitability as a store of value and medium of exchange. Thus, the precious metals more and more supplanted previously existing moneys. The culmination of the process was the establishment of gold and silver as money throughout the civilized world.

The growing demand for precious metals as a store of value and as a medium of exchange operated to prevent the kind of sudden substantial changes in value to which most other commodities are subject. For now changes in the supply of the precious metals did not have to be taken out of, or added on to, merely a relatively narrow commodity usage, but the increasingly broad usage as a store of value and medium of exchange as well. The demand for these purposes tends to be more stable than an ordinary commodity demand. Furthermore, the existence of a large accumulated stock of precious metals relative to their annual production operated greatly to mitigate the effect of changes in their annual production on their overall supply. For example, a 10 percent increase or decrease in the annual production represents approximately only a 1 percent increase or decrease in the total supply if the accumulated stock is on the order of nine or ten times the annual production. In addition, the extent to which the precious metals are used as ordinary commodities relative to their use as a store of value and medium of exchange is much smaller than could ever be the case with base metals such as iron or copper, and therefore, their value is correspondingly more stable.

Because of the relative stability of their value, the precious metals came to be a preferred medium in which to write contracts and state debts. In turn, the development of a class of people with obligations payable in the precious metals made them eager to exchange their goods and services for the precious metals, so that they would have the means of meeting their obligations. This, too, obviously contributed to the development of the precious

metals into money.

Coinage—the certification of the weight and fineness of specific pieces of the precious metals—followed their widespread use as a store of value and medium of exchange. Coinage performed the valuable function of sparing people the need to weigh and test individual pieces of metal. Instead, they could simply visually inspect the coins and count them out in making payment. Interestingly, the names of leading monetary units originally meant nothing other than definite weights of precious metal. For example, an English pound (in France, a *livre*; in Italy, a *lire*) meant an actual pound's weight of pure silver on the troy scale. The original English penny contained an actual penny's weight—one 240th of a troy pound—of pure silver.

In the Western World, gold and silver coins were money from the time of the early Roman Republic down to the twentieth century. (The period of the Dark Ages represented a hiatus, in which the economic system operated at an extremely primitive level, virtually without money and with hardly any division of labor.)

In modern times, starting very slowly, and gradually accelerating in the sixteenth and seventeenth centuries, and then more rapidly accelerating in the eighteenth and nineteenth centuries, the use of paper money developed. Paper money came into existence as transferable claims to gold and silver coins that were payable on demand to the holders of the paper. The practice developed of people leaving gold and silver on deposit with smiths, for safe keeping. In exchange, they were issued receipts. When these receipts were issued for specific sums, such as one pound, and, at the same time, were transferable, they were the ancestors of our present-day paper currency. When they were issued in a form that allowed the owner of the deposit to draw drafts on (i.e., write orders to) the smith specifying the amount to be paid to a specific individual, they were the ancestors of our present-day checking accounts. The smiths themselves, of course, were the ancestors of modern bankers.

Over the course of centuries, as the result of steadily increasing government intervention in their favor, paper currency and checks gradually displaced gold and silver in active circulation—to the point where, today, several generations of people have grown up with the experience of government paper as a universally acceptable medium of exchange. Today, everyone is willing to accept paper money in payment for his goods because he has had the constantly repeated experience, and thus has the expectation, that everyone else is willing to accept it and thus that he can use it to obtain whatever goods or services he wishes.

In the United States, a critical step in the displacement of the precious metals by paper occurred in the Civil War,

as the result of the government's issuance of greenbacks and then the enactment of the National Bank Act of 1863. Prior to the Civil War, the federal government was held to be constitutionally prohibited from issuing paper money, as were the states. Thus, from the enactment of the Constitution down to the Civil War, the only governmentally issued money in the United States was gold and silver coin. Banknotes—that is, privately issued paper currency—as well as checkbook money, were the liability of thousands of separate private banks. Because of the vast number of different kinds of banknotes, each with a different appearance, size, and color—in other words, a variation comparable to that between the stock certificates of today's corporations—the circulation of banknotes was strictly limited. Large manuals, comparable to today's *Moody's* or *Standard and Poor's* were required to keep track of the financial condition of the various banks issuing the notes, with the result that outside of the immediate locale of the issuing bank, banknotes were accepted only by experts or at a steep discount. Only gold or silver coin were universally acceptable. These facts underlay a substantial demand for gold or silver coin as a means of exchange.¹³

The greenbacks and the National Bank Act changed that. The National Bank Act placed a prohibitive tax on the issuance of private banknotes and instead made possible the issuance of national banknotes. Those banks which joined the newly created national banking system were entitled to issue national banknotes, which were backed partly by gold and partly by government securities. These notes had a uniform size, color, and appearance. Though technically issued by the separate national banks, they were actually a government paper currency. The establishment of redeemability of the greenbacks into gold in 1879 further strengthened the movement toward paper money.

The effect of a government paper currency redeemable in gold was that the demand for actual gold coin fell. People regarded the paper as equivalent to gold—as “as good as gold”—and increasingly used the paper in place of gold. Decade by decade following the Civil War, the quantity of gold coin in actual circulation steadily diminished. The gold was deposited in the banking system. The smaller banks redeposited it with the larger banks. By the time of World War I, almost all of the country's gold supply was held by the banking system, most of it by a small number of very large banks in New York City.

The Federal Reserve System was established in 1913. During World War I, an amendment to the Federal Reserve Act required that the banks turn over their gold to the Federal Reserve Banks, in exchange for checking deposits with the Federal Reserve Banks. Thus, practically all of the country's gold came into the possession

of the government during World War I. In 1933, under the New Deal, the government seized the remaining privately held gold at the same time that it abolished the domestic redeemability of the dollar—i.e., the right of holders of paper money to redeem their paper at the rate of one dollar for approximately one-twentieth of an ounce of gold.

The government's rationale for the seizure of privately held gold during World War I was its alleged need to be able to increase the quantity of money at a more rapid rate than would otherwise have been possible. This was held to be necessary to finance the war effort. On the basis of a mechanism to be explained shortly, and whose operation rested on government intervention, the private banking system had gained the ability to use gold in its possession—that is, its gold reserves—to support a quantity of paper-money claims to gold approximately four times as great. Substituting checking deposits with the Federal Reserve System for gold reserves left this four-to-one ratio on the part of the private banking system intact and, at the same time, made possible a vast expansion in bank reserves. Because now the Federal Reserve System could use the gold in *its* possession to increase the reserves of the banks in approximately a four-to-one ratio to its gold holdings. Thus, the same amount of gold was enabled to support approximately sixteen dollars of paper claims to gold instead of only four dollars of paper claims to gold. (This process is known as the pyramiding of reserves.)

In 1933, the government's rationale for the seizure of the remaining privately held gold was that its plan to increase the official price of gold above the then-prevailing \$20.67 per ounce would otherwise create a corresponding “windfall profit” for private owners of gold. The more fundamental and by far the more important motive, however, was, once again, the desire to be able to increase the supply of money more rapidly than would otherwise have been possible. At an official price of \$35 per ounce—the price prevailing from 1935 to 1968—the same physical quantity of gold was made capable of supporting correspondingly more paper dollars.

Contrary to the fears of some people at the time, the paper money did not immediately become worthless, even though it was no longer redeemable in gold. This was because several decades had gone by during which people had come to think of the government's paper as money. Two generations had grown up observing the general use and acceptability of paper money. It was the paper, not the gold, that they observed everyone being willing to accept, and which, therefore, they themselves desired as the means of making purchases. Thus, even though paper money lost its redeemability in gold, without which it could never have come into existence in the

first place, almost all of the demand for it remained, with the result that it did not go out of existence with the loss of that redeemability.

In the later thirties and during World War II, the U.S. government came into possession of a vastly larger quantity of gold, as the gold holdings of the European nations were run down by their policies of rapid inflation, their need to import vital supplies from the United States, and the desire of their citizens and governments to have a haven secure from foreign conquest. Together with the rise in the official price of gold from \$20.67 to \$35 per ounce, these enlarged gold holdings made it possible for a time for the U.S. government to go on increasing the quantity of paper money as rapidly as it wished. This could go on so long as the gold reserves owned by the U.S. government were larger than the gold reserves it was legally required to have—in other words, so long as it possessed *excess gold reserves*. For example, if the Federal Reserve System has outstanding \$50 billion of currency and checking deposits (the latter category held by banks as reserves) against which it is legally required to hold, say, \$15 billion in gold reserves, but it actually possesses \$25 billion in gold reserves, it is in a position to expand the currency and reserves of the banks by an additional two-thirds before its gold reserve requirement becomes an effective limit on its ability to create money.

Thus, the U.S. government was in a position to create money during World War II and for approximately two decades following World War II, even though it was nominally on a form of gold standard. Finally, however, once the reserves of the banks and the paper currency were expanded sufficiently, the gold reserve requirement had to become effective. Indeed, the date of its becoming effective was accelerated by the government's policy of trying to maintain a quasi-free-market price of gold of \$35 per ounce, which it did in order to try to make good the claim that internationally the dollar was "as good as gold." (Under the Bretton Woods agreement of 1945, the dollar was to be internationally convertible to gold and was to be the principal monetary reserve behind most other currencies.)

The U.S. government lost a major portion of its gold reserves in attempting to maintain the \$35-an-ounce price in the London gold market, which was reopened in 1951. In this market, governments and private individuals from around the world were free to buy and sell gold. (American and British citizens were excluded from the market, however. It had been illegal for American citizens to own gold for monetary purposes since 1933.) Whenever the demand for gold threatened to outrun the supply at a price of \$35 per ounce, the U.S. government simply dipped into its gold reserves and supplied what-

ever amount of gold was necessary to maintain the \$35-an-ounce price. As time went on, however, it became necessary to supply ever larger amounts of gold to keep the price at the \$35 level.

The policy of attempting to maintain the \$35-an-ounce price was doomed from the beginning, because so long as the supply of money grows more rapidly than the supply of gold, a fixed price of gold means that gold tends to become cheaper and cheaper compared with other goods whose price the more rapidly growing quantity of money tends to raise. The consequence must be a steadily growing industrial demand for gold. The growing industrial demand for gold would alone have eventually absorbed the government's gold reserves. But the process was accelerated by the fact that people recognized in advance what the ultimate result must be, and so began buying gold in anticipation of its ultimate rise in price. Such additional buying was denounced at the time as "speculative runs," but it was nevertheless perfectly reasonable in view of the underlying circumstances.

By 1965, the government's loss of gold had reached the point where it became necessary to abolish the gold reserve requirement that until then had been imposed on the Federal Reserve System. This became necessary in order for the expansion in the supply of dollars to continue. In 1968, the government abandoned the policy of selling gold to maintain the \$35-an-ounce price on the London gold market. In 1971, it abandoned its obligation to redeem dollars held by foreign governments or central banks. Since that time, the price of gold has greatly increased, reaching a peak of approximately \$800 an ounce in early 1980. As these words are written, it is approximately \$400 an ounce.

Since 1975, it has once again become legal for American citizens to own gold for monetary purposes. It has also become legal once again to write contracts that make debts payable in terms of gold. (This last provision still lacks real substance, however, since it is far from certain that the courts would enforce such contracts. Also, taxes would be incurred on the dollar income resulting from a rise in the price of gold.)

The Potential Spontaneous Remonetization of the Precious Metals

For reasons to be explained in Chapter 19, a policy of inflation destroys the real profitability of the traditional forms of investment, such as bonds, stocks, and family businesses. The monetary value of such investments tends not to keep pace with the rise in prices. This makes it necessary for people who want to preserve the buying power of their wealth to seek out assets whose price will rise in pace with prices in general and whose costs of maintenance and storage are minimal. In the circum-

stances of most people, gold and silver are the ideal candidates—for the very same reasons that made them the leading store of value in earlier periods of history.

Thus, as inflation becomes perceived as a serious problem, a growing demand for gold and silver develops as an “inflation hedge”—i.e., as a store of value. Once this demand reaches a certain level, the stage becomes set for a *spontaneous remonetization of the precious metals*. For, just as in the process by which the precious metals became money in the first place, once enough people want to own gold and silver as an inflation hedge and thus are willing to accept them in exchange for their own goods and services, others become willing to accept them too, even though they themselves do not wish to hold them as an inflation hedge or store of value. Conditions exist, in other words, for a growing acceptability of the precious metals, to the point at which they become universally acceptable, i.e., become money once again.

It should be realized that the remonetization of the precious metals would be greatly accelerated if they were allowed to compete with paper money freely. There exist large quantities of gold and silver coins minted both when they served as actual money and more recently as “restrikes,” that is, reproductions of the older coins.

The way the freedom of competition would accelerate the remonetization of the precious metals can perhaps best be understood by thinking back to the year 1965, when silver coins were still in actual circulation in the United States. At that time, a \$10 roll of silver quarters and a \$10 bill could be used interchangeably to buy a quantity of groceries, say. By the mid-1980s, that same quantity of groceries cost about \$30 in paper money. But the roll of silver quarters physically contained about seven ounces of pure silver. This means that at a market price of silver of \$6 per ounce, which prevailed in the mid-1980s, the \$10 roll of quarters had a market value of \$42 based on its silver content. Thus, the purchase price of \$30 for a given quantity of groceries represented less than *three-fourths* of a roll of silver quarters, or, looked at in terms of the face value of the quarters, less than \$7.50 in terms of silver coins. If merchants had been legally allowed to discriminate between paper money and precious-metal coins, they would have sold the same quantity of groceries either for \$30 in the paper money or for less than \$7.50 in the silver money.

The same principle applies even more strongly in the case of our old gold coins. Prior to 1933, the United States had gold coins, known as double eagles, which had a face value of \$20 and contained just under an ounce of pure gold. At today’s price of gold of almost \$400 per ounce, a new automobile that sells for \$12,000 in paper money would sell for about \$600 in gold coin. (At the current market price of gold bullion of almost \$400 per

ounce, thirty \$20 gold coins, each containing an ounce of gold, simultaneously represent \$600 in gold and \$12,000 in paper.)

Such facts would make it very obvious to the general public precisely where the problem of rising prices lay—namely, in the paper money. And this knowledge, in turn, would operate to reduce the demand for paper money and increase the demand for precious-metal money. People would want to have their pensions payable in gold or silver. Creditors would want the money due them to be stated in gold or silver. This, of course, would further increase the demand for precious metals and decrease the demand for paper money. In an environment of prices steadily rising in paper money, but constant or, more likely, falling in precious metal-money, the demand for paper money would soon be wiped out altogether. Just as people prefer a better soup or automobile to a poorer soup or automobile, they prefer a better money to a poorer money. Under free competition, the only way paper money could stay in circulation would be by being made redeemable in the precious metals.

This discussion may appear to contradict Gresham’s Law. It shows that under free competition “good money drives out bad money,” while Gresham’s Law states that “bad money drives out good money.” There is no contradiction when it is realized that Gresham’s Law applies to circumstances in which the freedom of competition is prohibited. What drives out good money is the fact that businessmen are prohibited from accepting it at its actual value. This is the case today. Any buyer who wished to buy with gold or silver coins today would be required to use them as though they were worth no more than the paper money. To buy a \$12,000 automobile with double eagles, the buyer would be required to pay six hundred such coins, for this is the quantity that is required to have a face value of \$12,000. In other words, he would be required to part with gold that had a market value of \$240,000, in order to buy something worth only \$12,000. The buyer using silver coins in our groceries example would be required to part with three rolls of quarters, having a market value of \$126, in order to buy \$30 worth of goods. Under such conditions it is not difficult to understand why the better money ceases to circulate as money. People will not sacrifice what is better when it is treated equivalently to what is poorer. But when what is better can be treated as better, as when gold and silver coins can circulate at their bullion value, then, indeed, good money drives out bad.

The Government and the Banking System

It is impossible to understand the extent to which the government has increased the quantity of money without understanding how the government has encouraged the

creation of money by the private banking system.

What we must deal with here is how the government has encouraged the existence of what von Mises calls “fiduciary media.”¹⁴ Fiduciary media are *transferable claims to standard money, payable by the issuer on demand*, and accepted in commerce as the equivalent of standard money, but for which no standard money actually exists. The larger part of our money supply today consists of fiduciary media in the form of checking deposits.

Standard money in contrast is money that is not itself a claim to anything further. It possesses ultimate debt-paying power, in that when it is received no further claim to be paid is present. Under a gold standard, standard money is gold. Any paper money that exists is a claim to it. Under a system of irredeemable paper money—fiat money—the irredeemable paper money is the standard money. In the present conditions of the United States, the standard money consists of the supply of Federal Reserve notes and, for all practical purposes, the checking deposit liabilities of the Federal Reserve System, which are fully equivalent to the notes. It is essentially the same as what is referred to as “the monetary base,” which is the sum of currency in circulation outside banks plus bank reserves.

An analysis of the composition of the present U.S. money supply will make the concept of fiduciary media clearer. As previously stated, the total U.S. money supply at the end of 1993 was \$1,128 billion, and of this, \$799 billion were in the form of checking deposits held at the various banks.

Now, checking deposits are not standard money. They

are a liability—a *debt*—of the various banks. They are a promise of the banks to pay standard money on demand to their depositors. They circulate as the equivalent of standard money so long as no one questions the ability of the banks to meet that promise. Against these \$799 billion of checking deposit liabilities the banks held on the order of \$60 billion of standard money as reserves—partly in the form of currency in their actual possession, partly in the form of deposits with the Federal Reserve System.¹⁵ Thus, \$799 billion of checking deposits were backed by \$60 billion of standard money. The difference—\$739 billion—represents fiduciary media. Fiduciary media are the portion of checking deposit liabilities of the banks not covered by standard money.

Fiduciary media under present conditions come into existence in either of two ways. One way is the lending out of standard money that has been deposited in checking accounts. The other way is the creation of new and additional checking deposits without benefit of new and additional standard money. Let us consider an example of each, as illustrated in Figure 12–1, which shows so-called T-accounts for the public and the banking system.

Figure 12–1 shows an individual who deposits \$100 of standard money into his checking account. In doing this, the individual does not part with the use of his money, because he can spend the checking deposit itself. He is minus currency in the amount of \$100 but plus a checking deposit in the amount of \$100, which is shown on the very next line. His action represents merely a change in the form in which he holds his money. It is equivalent in principle to exchanging a ten dollar bill for

Figure 12–1
The Creation of Fiduciary Media

<i>The Public</i>	
Assets	Liabilities
Minus Currency \$100 (1) Plus Checking Deposit \$100 (1)	
Plus Currency \$80 (2), or Plus Checking Deposit \$80 (2a)	Plus IOU'S to Banks \$80 (2 or 2a)
<i>The Banking System</i>	
Assets	Liabilities
Plus Currency \$100 (1)	Plus Checking Deposit \$100 (1)
Plus IOU'S from Public \$80 (2 or 2a) Minus Currency \$80 (2)	Plus Checking Deposit \$80 (2a)

two fives. This transaction is labeled (1) in the T-account of the public and in the T-account of the banking system. The banking system is simultaneously plus \$100 in currency and plus a checking deposit liability of \$100, which entries are shown on opposite sides of the T-account.

If the bank now lends out any part of the \$100 of standard money that has been deposited, it necessarily increases the total quantity of money in circulation, because the depositor still has his \$100 that he can spend by writing checks, and the borrower from the bank now has whatever it lends him. A transaction in which the bank lends out \$80 is labeled (2) in the T-account of the public. The public is shown both to receive \$80 of currency and to become indebted to the banking system in the amount of \$80. (Again, these entries are shown on opposite sides of the T-account.) The same transaction is also shown from the point of view of the banking system, where it is also labeled (2) and describes how the banking system is plus \$80 in IOUs from the public and, on the next line, minus currency in the amount of \$80. The essential point is that the spendable funds of the public equal the sum of the \$100 they have deposited into a checking account plus whatever part of that \$100 they then borrow from the banking system. For both the funds they have deposited and the funds they borrow represent spendable money.

The second way in which fiduciary media are created arises because of the popularity of payment by check. The borrower in our example would probably not want currency; he would probably want to make payments by check. As a result, instead of lending him currency, the bank would credit his checking account with the proceeds of the loan. Observe. Here we have a new and additional checking deposit coming into existence without benefit of any additional quantity of standard money on hand. This transaction is labeled (2a) in the T-accounts. It shows the public as simultaneously plus \$80 in a checking deposit and, as before, plus \$80 in indebtedness to the banking system. The banking system is shown as plus \$80 in IOU's from the public, as before, and plus \$80 in checking deposit liabilities instead of being minus \$80 in currency. Again, just as when the bank lent currency, there are \$80 of additional spendable money.

Now, the supporters of fiduciary media are quick to point out that fiduciary media are not without backing of any kind. They are backed, they say, by the loans and investments banks make in creating them and by the capitals of the banks. For example, when a bank creates a checking deposit of \$80 for a borrower, the bank's assets also grow by \$80—the \$80 now owed to the bank by the borrower. And the borrower may have had to put up collateral worth more than \$80. In addition, the bank has its own capital that is lent out or invested, and this

provides further backing, it is argued. As a result, the \$733 billion of presently outstanding fiduciary media are backed by assets totaling more than \$733 billion.

And, of course, an alternative way of looking at fiduciary media is that of the fractional-reserve principle. For example, instead of viewing the present \$799 billion of checking deposits as representing \$60 billion backed 100 percent by standard money and \$733 billion backed by no standard money, one can view each dollar of checking deposits as backed by a uniform fraction of standard money—in our case, by $\frac{60}{799}$ of a dollar of standard money. The remaining $\frac{733}{799}$ of each dollar of checking deposits could be viewed as backed by the loans and investments of the banks. Whichever way we view them, fiduciary media are a kind of debt money. They are a debt of the banks, backed by debt, but circulating as money.¹⁶

The great problem of fiduciary media is that they set up money and debt like a house of cards or row of dominoes that any breeze can knock over. Observe. The safety and value of the fiduciary media are supposed to depend on the value of the assets behind them. What is overlooked by the supporters of fiduciary media, however, is that the value of the assets behind them depends on the continued existence of the fiduciary media themselves. To grasp this point clearly, let us assume that there is a failure of a single large bank that has issued fiduciary media. Such a failure could result from the failure of business enterprises to which the bank had made loans. The effect of the bank failure is actually to *reduce* the quantity of money in the economic system by the amount of that bank's checking deposits. Checking deposits held at a bank that has failed lose the character of money. They cease to be accepted as the equivalent of money in trade. Their status becomes that of an uncertain claim against the bank—a claim that may or may not be paid, to some unknown extent, at some future time.

Now, if the quantity of money actually falls, then, the quantity theory of money tells us, the demand for goods must fall. And as demand falls, the money revenues of businesses and the money incomes of individuals fall, because they are constituted by demand. As their revenues and incomes fall, the ability of people to pay debts falls, including, of course, their debt to banks. At the same time, the effect of a reduced quantity of money is to reduce the market value of assets that banks hold as collateral, such as stock-market collateral and the value of the property on which they hold mortgages. It is very easy, therefore, for the failure of one bank that has issued fiduciary media to cause the failure of several others—because the wiping out of its fiduciary media endangers the money value of their assets, on which their fiduciary media rest.

Indeed, once started, the process of bank failures tends to gain momentum: an initial failure wipes out money, which reduces the ability to spend money and thus to earn money and repay debts. The reduction in the ability to repay debts reduces the income and assets of banks and this in turn causes more bank failures and wipes out more money, with the effect of still greater declines in spending, sales revenues and incomes, asset values, and thus the ability to repay debts. Once begun, the process can lead, and again and again in our history has led, to periods of major deflation following periods in which the money supply was first inflated in the form of fiduciary media. The last such period of deflation was 1929 to 1933, following the expansionary period of World War I and the 1920s. In that period, the quantity of money fell by more than 25 percent and the volume of spending, as gauged by GDP, fell by almost 50 percent. Today there is even more massive deflationary potential than in 1929 because a much longer, far greater expansion of fiduciary media has occurred than in the years prior to 1929.

It must be said immediately, however, that no one should expect the deflationary potential of our day to be realized, because today, unlike 1929, the Federal Reserve System has unlimited power to expand the quantity of standard money. It will almost certainly do so to whatever extent is necessary to prevent a reduction in the quantity of money. Normally, when a bank fails nowadays, arrangements are made for it to be taken over by another bank, without loss to its depositors. In recent years there have been a few cases of losses to depositors who held over the insured amount of \$100,000, but in no case has this occurred at a major bank. Indeed, when Continental Illinois National Bank, one of the country's major banks, was in danger of failing some years ago, the Federal Reserve and FDIC (Federal Deposit Insurance Corporation) made clear their willingness to make available however many billions of dollars might be necessary to prevent the failure.

This means that the government's policy of money creation—of inflation—will continue and almost inevitably accelerate. Nevertheless, the Continental Illinois case still confirms the existence of the domino effect I have described. It was rescued precisely in order to avoid that effect. Its failure would have precipitated runs on other financially troubled banks. A substantial volume of checking deposits would have been wiped out, correspondingly reducing the quantity of money and volume of spending in the economic system. The consequence would have been the onset of a major depression, accompanied by waves of bank failures.

Economists who have recognized the inherent danger of fiduciary media, and who believe that there is no advantage to a country in a quantity of money that

expends any more rapidly than gold and silver, have come to the conclusion that the ideal monetary system would be a *100-percent-metallic-reserve system*. Under this system, all paper currency and checking deposits would be 100 percent backed by gold or silver. The advantage of such a system would be that not only would it be immune from inflation, but, unlike the fractional-reserve gold standard of the nineteenth century and the first decades of this century, it would also be immune from *deflation*. Because once gold or silver money comes into existence, it *stays* in existence. It is not wiped out by the failure of any debtor. Under such a system, financial failures do not become cumulative self-reinforcing waves. Such a system would offer the maximum of monetary stability.

The 100-percent-reserve system is logically urged only for checking deposits and banknotes (currency), *not* for savings deposits or time deposits. There is a crucial difference in that savings and time deposits do not represent spendable money as such. When an individual makes a savings deposit or a time deposit, he temporarily gives up the use of his money. He cannot spend the savings or time deposit as such. If he wants his money, he must go and withdraw his deposit or wait until it matures. He must obtain actual money. When a bank lends the proceeds of a savings or time deposit, therefore, it is *not* engaged in the creation of money, but merely in the transfer of a given amount of money from a lender—that is, the savings or time depositor—to a borrower. Under the 100-percent-reserve system, therefore, banks would continue to lend out savings and time deposits, just as now. For the rest, they would earn money by charging fees for the storage of precious metal, its transfer from checking account to checking account, the issue of banknotes, and whatever other services they might perform.¹⁷

The supporters of the 100-percent-reserve principle divide into two groups. There are those who advocate its imposition by law. Those among this group who are committed to the principle of individual rights and *laissez-faire* capitalism justify this by claiming that the creation of fiduciary media is tantamount to counterfeiting and is fraudulent. They claim that it is the same in principle as accepting goods in a warehouse, issuing receipts for the goods, and then selling the goods; or selling more tickets to a theater performance than there are seats.¹⁸

The second group holds that if the issuance of fiduciary media is conducted openly, without deception—that is, if it is no secret to the owners of banknotes and checking deposits that the backing for them is debt—one cannot outlaw the practice. These supporters of the 100-percent-reserve principle advocate its achievement by

means of a policy of *free banking*—that is, merely the total absence of all government intervention in banking. This view is well expressed in a passage quoted in von Mises's *Human Action* from the nineteenth-century French economist Cernuschi. It was made in reference to fiduciary media in the form of banknotes, but it applies equally to fiduciary media in the form of checking deposits as well. Cernuschi said: "I want to give everybody the right to issue banknotes so that nobody should take any banknotes any longer."¹⁹

In what follows, I content myself with providing an elaboration of the position of the second group of the supporters of the 100-percent-reserve principle—namely, the view that in an economy that was free of government interference in money and banking, the creation of fiduciary media would be legal, but for all practical purposes would not take place. This view is supported by such facts as that any granting of fiduciary media would place the customers of the banks that granted them in a position to expand their purchases from the customers of banks that did not grant them or granted them less rapidly, because such customers would have relatively more money to spend. The effect would be an adverse clearing balance against the expanding, or more rapidly expanding banks, which would thus lose reserves to the sounder banks.

The problems of the expanding banks would be further compounded by the existence of a growing demand for gold and silver coin on the part of the public. In conditions in which gold and silver coins are extensively used as money, this would occur as the by-product of any increase in the overall quantity of money. It would occur for much the same reasons as an increase in the demand for twenty dollar bills, say, when there is an increase in the quantity of money in the form of hundred dollar bills or ten dollar bills. Indeed, just as some of the hundreds or tens would be brought to banks for exchange into twenties, so, in an economic system in which gold or silver coin was extensively used, any increase in the supply of paper currency or checkbook money would necessarily be accompanied by the exchange of part of it for additional gold and silver coins, simply in order for people to maintain proper proportions among the different kinds of money they used. Such redemptions of currency and checkbook money, would, of course, represent an additional pressure on the banks' reserves if they pursued a policy of increasing the supply of paper or checkbook money.

Moreover, in a banking system totally unprotected and unsupported by the government—a banking system without any form of government controls, government inspections, examinations, assurances, guarantees, or endorsements—people would realize that when they made

deposits in banks that did not hold a 100 percent reserve, they were in fact taking some risk of loss. They would realize that what they were doing was granting credit, not holding money, and that if they wanted to grant credit, they had better learn how to read a bank's balance sheet, how to evaluate it, and how to distinguish between good and bad banks. Those not prepared to do this, and whose real intention was to hold money, would realize that if that is what they wanted to do, they should hold deposits at 100-percent-reserve banks. The transferable deposits of fractional-reserve banks would cease to be regarded as money. They would be regarded as credit instruments, to be held only by those prepared to grant credit, not by people desiring to hold money.

All along, however, the government has sought to encourage the existence and growth of fiduciary media. The government has acted in the belief that the mere expansion of bank credit—i.e., the creation and lending out of fiduciary media—could create real capital goods and thus generate prosperity. From the beginning, the government was urged on and applauded by businessmen seeking lower rates of interest—seeking what they call "easy money." What actually happened, of course, was not prosperity, but the trade cycle.²⁰

In the eighteenth and nineteenth centuries, fiduciary media were encouraged by the existence of government-supported central banks, such as the Bank of England and, in this country, the First and Second Banks of the United States. So long as the central banks were and are able to go on creating reserves, banks are rescued from the loss of reserves they would otherwise experience as the result of an adverse clearing balance with other banks. They are able to obtain fresh reserves, and in an even larger quantity. To the extent that the government or its central bank is able to substitute the use of its paper currency for gold and silver coin, it also reduces the pressure on reserves of a greater need for currency to keep pace with the overall growth in the quantity of money taking place. For the government can manufacture whatever additional paper currency it may wish, to replace lost reserves, while it cannot manufacture additional gold and silver coin as it may wish.

Again and again, when banks did fail, the government stepped in and allowed them to suspend payment in specie, in flagrant violation of their agreement to pay their depositors specie on demand. This prevented the wiping out of fractional-reserve banks and enabled such banks to return to issue still more fiduciary media. Restrictions on the formation of new banks and on the expansion of more conservatively managed existing banks—the latter in the form of restrictions on branch banking—also served to promote the existence of fiduciary media. This was the result insofar as the effect of the free competition

of such banks, if it had been allowed, would have been a greater problem of adverse clearing balances for banks expanding their issue of fiduciary media. In addition, all government measures that built confidence in the banking system, such as imposing minimum capital requirements, double liability for bank stockholders, and bank examinations, also importantly aided in the promotion of fiduciary media in the eighteenth and nineteenth centuries.

In this century, the government has encouraged the expansion of fiduciary media principally through the Federal Reserve System. The Federal Reserve System has supplied the banking system with vastly larger reserves of standard money in the form of Federal Reserve notes and deposit credits than it could possibly have acquired if its reserves had had to be in a standard money of gold, as was the case before World War I. This more rapid growth in bank reserves of standard money has been a necessary foundation for the more rapid growth in checking deposits, because the deposits banks can create are always tied to the amount of standard-money reserves at their disposal. With more reserves, they can support more deposits, and so they create more deposits.

In addition, the government, again operating largely through the Federal Reserve System, has made it possible for any given volume of reserves to support a larger volume of deposits. It has done this by virtue of following one of the avowed objectives of the Federal Reserve's foundation, which was to act as a "lender of last resort" to the commercial banks. The Federal Reserve System stands ready to lend standard money to the banks or buy assets from them whenever they require. This permits the banks to hold such assets as the Federal Reserve will lend money on or buy, in place of holding actual standard-money reserves. The result is an expansion of deposits relative to reserves, because when the banks acquire these assets, the sellers usually take the proceeds of their sale and bring them back to the banking system in the form of fresh deposits. For example, if a bank buys a Treasury bill, say, or commercial paper, in the knowledge that it can obtain standard money from the "Fed" by means of these assets, the seller of the asset now has standard money. He will almost certainly deposit this standard money in some bank. The effect is that the banking system now ends up with more deposits and with just as much standard money as it had initially. Thus, the same reserves of standard money now support a larger volume of deposits.

Finally, the government has further promoted the existence of fiduciary media in this century through such measures as deposit insurance, increased governmental supervision of banks, and increased control over the nature of the loans and investments banks can make. All

of these measures promote confidence in fiduciary media by virtue of the government's word rather than by virtue of the fact of financial soundness. If not for these and other such measures that I have described, some of them going back even before the nineteenth century, banks would have to hold far larger reserves in relation to checking deposits to instill the same degree of confidence.

In all of these ways, therefore, the government has been responsible for the creation of fiduciary media. It is against this background that the imposition of legal minimum reserve requirements by the Federal Reserve System must be viewed. For example, currently the Federal Reserve requires that on checking deposit liabilities in excess of \$51.9-million, banks hold an amount equal to a minimum of 10 percent of such deposits as a reserve, in the form of currency on hand or checking account balance with the Federal Reserve.²¹ This requirement exists in a situation in which current market conditions would enable the banks to get by with a smaller percentage of reserves. The preceding discussion makes it clear, however, that it would be a profound mistake to conclude from these facts that government intervention operates to impose higher reserve requirements than would a free market. For the imposition of the reserve requirements takes place in a context in which generations of government intervention, including the intervention directly carried out by the Federal Reserve System, has radically reduced the reserves that are required in current market conditions, which market conditions fully reflect the government's intervention. The Federal Reserve's minimum reserve requirements merely serve to prevent the banks' reserve ratios from declining quite as far as all the other government intervention has made it possible for them to do.

On the basis of its responsibility for the creation of fiduciary media, the government must bear the responsibility for the boom-bust pattern of our economic history. In addition, of course, its promotion and support of fiduciary media have played a major role in the rapid increase in the quantity of money that has taken place in recent decades. Today, by virtue of the government's unlimited ability to create standard money and to supply it to banks in need of it, and by virtue of its commitment to do so, fiduciary media can be considered as practically the equivalent of standard money created by the government itself, that is, as part of the overall supply of fiat money.

In the light of recent developments, this last statement must be qualified with respect to checking deposits held in smaller banks. As the result of substantial losses, and spurred on by recent legislation, the Federal Deposit Insurance Corporation has increasingly refused to make

good depositors' losses on bank accounts in excess of \$100,000, which is the current legal limit of its obligation. However, in the case of large banks, where a substantial number of depositors would be involved, the policy of the FDIC still appears to be that of making good all losses of depositors, irrespective of the amount.²² Moreover, the Federal Reserve System is still in a position to rescue any bank it wishes, simply by providing the necessary funds either as a loan or as a purchase of assets.

Today, money is created in the first instance primarily by means of the so-called open market operation of the Federal Reserve System. That is, the Federal Reserve System enters the government securities market and buys outstanding government securities with standard money that is newly created, virtually out of thin air. When the sellers of the securities deposit the proceeds in their banks, the banks obtain additional deposits and equivalent additional reserves of standard money. On the basis of their additional reserves, they in turn create additional fiduciary media, whose redeemability in standard money is, of course, virtually guaranteed by the government, with the limited exception just mentioned. Government deficits are a constant source of new government securities, and for all practical purposes can be viewed as being financed directly by the Federal Reserve System, just as in the example of the social security checks earlier in this chapter.

Apart from ceasing all of its intervention in favor of fiduciary media, including its issuance of paper currency, there is one further important and totally legitimate step the government could take, short of prohibiting fiduciary media outright on the grounds of fraud. This is to follow the example of President Andrew Jackson's specie circular and refuse to accept checks or private banknotes that are not 100 percent backed by gold or silver. To accept such checks or banknotes places the government in a position in which it can be construed as granting credit to the banks in question—in which, according to the supporters of fiduciary media, it *is* granting credit to those banks, inasmuch as it knowingly accepts claims that do not represent actual money, but largely debt. The government has no business granting credit to anyone. By all the ordinary principles of *laissez faire*, it should not be in business of any kind; it should not be a lending agency of any kind. The only way it can unequivocally avoid granting credit is if, insofar as any money is due it, it requires payment in specie or in notes or deposits that are 100 percent backed by specie. When it receives such money, it is fully and finally paid; in that case, no question can arise of its granting credit. Such a policy by the government would all by itself do a great deal to restrain the issuance of fiduciary media. Added to con-

sistent abstention from all other acts favoring fiduciary media, it could well make their issuance virtually impossible.

3. The Quantity of Money and the Demand for Money

The volume of spending in the economic system is determined not only by the supply of money—the quantity of money—but also by the *demand* for money. The demand for money refers to the extent to which people desire to hold balances of money relative to the receipts they take in and the sums they pay out. People need to hold money in order to make purchases and pay bills in the future. Under varying circumstances, they choose to make a larger or a smaller demand for money. The greater is the demand for money, the greater are the balances of money that people wish to hold relative to their receipts and expenditures. The smaller is the demand for money, the smaller are the balances of money that people wish to hold relative to their receipts and expenditures.

It should be obvious from these statements that the so-called velocity of circulation of money is determined by the demand for money. The greater is the demand for money, the lower is the velocity of circulation of money. The smaller is the demand for money, the higher is the velocity of circulation of money.

The reason for this relationship between velocity and the desire to hold money can be understood by considering the case of any given individual who owns money. Imagine an individual who owns \$1,000 in the form of currency or a checking-account balance. If this individual feels that he needs to hold, say, \$700 out of his thousand in order to make purchases or pay bills in the period starting one week from the present, then the most he can afford to spend out of his thousand dollars this week is \$300. If, however, he should decide that he only needs to hold, say, \$600 for the period starting a week later, then, this week, he could afford to spend \$400 out of the thousand he owns. Clearly, the individual's ability to spend the money he owns is the greater, the less of it he needs or desires to hold for the future; and is the smaller, the more of it he needs or desires to hold for the future.

It follows that anything that occurs which makes individuals decide to reduce the cash they hold for the future will increase spending and therefore velocity. By the same token, anything that occurs that makes individuals decide that they need to increase the cash they hold for the future will reduce spending and therefore velocity.

To quantify the relationship between the demand for money and the velocity of money more precisely, a so-called income velocity of 4 reflects the fact that people want to hold balances of money equal to $\frac{1}{4}$ of

their annual incomes and consumption expenditures. The higher income velocity of 6 reflects a lower demand for money balances, equal to only $\frac{1}{6}$ of people's annual incomes and consumption expenditures. The lower income velocity of 3 reflects a higher demand for money balances, equal to $\frac{1}{3}$ of people's annual incomes and consumption expenditures. Whenever the demand for money falls, people step up their expenditures out of their existing cash holdings, and thus velocity rises. Whenever the demand for money rises, people cut back on their expenditures, in an effort to increase their cash holdings, and thus velocity falls.

The demand for money is determined by a variety of factors. One of the most important, and, indeed, the most fundamental, is the security, or lack of security, of property. Where property is insecure—where it is subject to arbitrary confiscation by the government or to plunder by private gangs—saving and provision for the future will be low, because people will not be in a position to count on benefitting from it. But such saving and provision for the future as does occur will largely take the form of holding precious metals and gems—items easily concealable and easily transportable. A gold money in such circumstances has a very low velocity of circulation.²³

By the same token, under conditions in which property is secure from confiscation and plunder, the demand for gold for holding will be less, and thus the velocity of circulation of a gold money will be greater. The same result is aided by the development of financial markets and financial institutions, which make it easier and more profitable for people to invest their savings rather than hold them in the form of precious metals or precious stones.

Interestingly, the effect of lack of security of property is very different on a paper money than on a gold money. In conditions in which a government loses the power to stop private plunder or itself becomes a looter, people switch their savings from assets denominated in the government's paper to precious metals and precious stones. They lose the desire to hold such paper, because it becomes more and more likely that the government will sharply reduce its value by rapidly increasing its supply. Thus, the velocity of a paper money tends to rise in such circumstances.

The velocity of money can also be increased by such developments as improvements in transportation, which reduce the time money is in transit and correspondingly increase the speed with which it is available for respending. The development of clearing houses reduces the amount of money that is required to perform a given volume of transactions: instead of all of the transactions needing to be effected by means of the transfer of money, only the settlement of the net amounts owed or owing,

after the canceling of offsetting debts by the clearing process, needs to be effected by means of the actual transfer of money. The money set free by the clearing process is thereby made available for spending for other things. Thus, the total spending that the same quantity of money can effect is increased.

What is especially worthy of note is the fact that in the context of an economic system with developed financial institutions and financial markets, *saving* operates to raise the velocity of circulation of money. (This may be the cause of some surprise, in view of the popular fallacy that confuses saving with hoarding.) There are two reasons for this. First, under such conditions funds that are saved are likely to be made available for spending sooner than funds that are held for consumption. For example, the part of his paycheck that an individual deposits in his savings account is available for lending by the bank almost immediately. However, the part of his paycheck that he retains in his possession in the form of cash that he plans to spend on consumers' goods in the coming days or weeks prior to his receipt of his next paycheck will enter into the hands of others only over the length of this considerably longer period. Second, to the extent that the availability of additional savings contributes to credit being readily available, it becomes possible for individuals and business firms to substitute to some extent the prospect of obtaining such credit for the holding of money as the means of providing for their future need for funds. To this extent, they reduce their cash holdings and thus bring about a rise in the velocity of circulation of money.²⁴

It should be realized that in the conditions in which the velocity of circulation of a gold money rises, there is unlikely to be any fall in the purchasing power of gold as a result. This is the case because the rise in velocity here is the accompaniment of a process that sharply increases the physical ability to produce—above all, the growth of saving and the channelling of those savings into productive investment. In addition, a further factor that must be mentioned, which is especially relevant in appraising the effects of the development of clearing procedures, is that the productive process also tends to become more complex at the same time that the demand for gold holdings falls. Because of the intensification of the division of labor, which is inextricably bound up both with the growth of saving and investment and the increase in production, a tendency exists toward an increase in the number of payments needed in the production and distribution of ultimate consumers' goods. For example, instead of a farmer selling his food to a consumer, he sells it to a food processor, who sells to a wholesaler, who in turn sells to a retailer. Possibly several processors and wholesalers are involved. The intensification of such

specialization and its requirement for additional acts of exchange more or less keeps pace with the decline in the desire to own balances of gold. Consequently, while the total of spending of all types combined rises relative to the quantity of gold, it does not follow that spending *specifically for consumers' goods* rises relative to the quantity of gold. In other words, the velocity that actually rises is the so-called transactions velocity, but not necessarily income velocity, or certainly not to the same degree. (Furthermore, it should not be assumed that either the fall in demand for gold holdings or the growth in complexity of the productive process necessarily goes on indefinitely.)

Changes in the Quantity of Money as the Cause of Changes in the Demand for Money

There is a further source of changes in the demand for money—a source that would probably not be present at all under a 100-percent-reserve gold standard, but which exerts an extremely powerful influence under a fractional-reserve gold standard and under a system of fiat paper money. This is *rapid changes in the supply of money itself*.

Under a 100-percent-reserve gold standard, the supply of money increases no more rapidly than the supply of gold, which increase is almost always quite modest.²⁵ Equally important, for all practical purposes, the supply of money can never *decrease* under a 100-percent-reserve gold standard. The gold that people take to the grave with them in such things as dental fillings is dwarfed by the current production of gold. The occasional ship or plane that goes down carrying gold, which gold cannot then be found or salvaged, is also not enough to make a difference. Thus, as stated before, once a gold money comes into existence, it *stays* in existence. It is not wiped out by the failure of any debtor.

Under a fractional-reserve gold standard, on the other hand, there are periods in which the money supply can be increased relatively rapidly, by means of the issuance of fiduciary media. In these periods, the increase in the supply of money corresponds not only to the increase in the supply of gold, but also to the decrease in the ratio of gold reserves. And then, of course, when banks fail and their fiduciary media lose the character of money, the money supply can sharply decline.

Under a system of fiat paper money, the money supply can be increased at any rate the government desires. For reasons to be explained later in this book, a powerful tendency exists under this kind of monetary system for the increase in the quantity of money to accelerate.²⁶ The only intrinsic limit to such acceleration is the total destruction of the demand for the money, at which point the money ceases to be accepted in payment and loses its

character as money. Examples of the process of an accelerating increase in the quantity of money carried to the point of the destruction of the fiat money concerned are the continental currency of the United States in the American Revolution, the French assignats during the French Revolution, the German mark following World War I, and the currency of nationalist China following World War II.

The connection between changes in the quantity of money and the demand for money is simply this: *the more rapidly the quantity of money increases, the lower tends to be the demand for it; the less rapidly the quantity of money increases, the higher tends to be the demand for it.*²⁷ In conditions in which the quantity of money actually decreases, the demand for money becomes all the greater. To state the relationship in terms of the velocity of circulation of money, the more rapidly the quantity of money increases, the higher tends to be the velocity of circulation of money; the less rapidly the quantity of money increases, the lower tends to be the velocity of circulation of money. In the face of a decrease in the quantity of money, velocity tends to be lower still.

We can find some immediate confirmation of this principle if we ask which currencies people prefer to own and why—for example, Argentine pesos, English pounds, or U.S. dollars? Obviously, the peso is the least desirable of the three currencies to own, and the dollar the most desirable. The reason the peso is the least desirable of the three to own is that it is the one whose quantity is most rapidly expanded and which therefore loses purchasing power the fastest. As a result, no one wants to own more than the barest minimum of pesos necessary to transact business in Argentina. The dollar, on the other hand, is the most desirable of the three to own, because its quantity is expanded the least rapidly and it therefore retains its purchasing power better than the others. Accordingly, among these three countries, the velocity of circulation of money is highest in Argentina and lowest in the United States. It is also higher in the United States today than it was in the United States in previous decades, when the increase in the supply of dollars was less rapid.

There are four avenues by which changes in the quantity of money affect the demand for money. Perhaps the most widely recognized is its effect on prices and the prospects for changes in prices. As was implicit in the previous paragraph, once an expanding quantity of money creates the expectation of rapidly rising prices in the future, people conclude that it pays to buy goods right away, before their prices rise further. They come to the conclusion that the continued holding of cash balances must cause them a substantial loss of purchasing power, and so they attempt to reduce their holdings of money. Conversely, the anticipation of a fall in prices in the

future, resulting from a contraction in the quantity of money and volume of spending, increases the desirability of owning money. In such circumstances, it pays people to postpone purchases in order to take advantage of lower prices in the future.²⁸

A second, closely related connection between changes in the quantity of money and the velocity of money concerns the ability to substitute holdings of other assets for holdings of money. If the quantity of money is rapidly increasing, it pays to hold other assets, such as inventories of various commodities, rather than money itself. In such circumstances, these other assets are a better source of meeting future needs for cash than the holding of money, because they can easily be sold for more money than they cost. This principle applies not only to businessmen holding inventories of commodities that they produce, but also to consumers. As inflation accelerates, it pays even the ordinary consumer to hold commodities as a source of future cash rather than cash itself—above all, gold and silver or less rapidly inflating foreign moneys.

Conversely, if the quantity of money decreases rather than increases, not only does the holding of commodities represent a financial loss while the purchasing power of money in contrast rises, but people also want to hold money even in place of such things as short-term securities and savings and time deposits. This is because in such circumstances—namely, a deflation and depression—people cannot be sure of converting these near moneys into actual money, since the issuer of the securities or the bank where one has the deposit may go bankrupt first. These are major reasons why periods of deflation—i.e., of a decrease in the quantity of money/volume of spending—are periods of an intensified desire to hold money, and, therefore, of a drop in the velocity of money.

The two remaining reasons why increases in the quantity of money tend to increase velocity, and why decreases in the quantity of money tend to reduce it, pertain to the effects of changes in the quantity of money on the availability of credit and on interest rates.

The desire to hold money—especially on the part of business firms—is largely determined by the prospective availability of credit. If credit is expected to be available easily and profitably when funds are required, the perceived need and thus the desire to hold money will be correspondingly less. If credit is expected to be unavailable or available only with great difficulty and at a loss when funds are required, the perceived need and thus the desire to hold money will be correspondingly greater. In effect, as we have seen, prospective credit that is readily and profitably available serves as a substitute for the holding of money.

Now the increase or decrease in the money supply is

a major factor determining the availability of credit at any given time. When the money supply is increasing, a very large portion of the increase usually enters the economic system in the form of new loans, with the result that credit is made easier. This is particularly true when the increase in the quantity of money takes the form of additional fiduciary media. It is what people have in mind when they talk of “easy money.” Conversely, when the money supply decreases, as in a depression accompanied by bank failures and the wiping out of fiduciary media, the decrease results in a sharp reduction in the availability of credit.

Thus, an expansion of the money supply reduces the perceived need to hold money through its effect on the current and prospective availability of credit. In an economy which has become accustomed to “easy money,” or which offers the prospect of “easy money,” businessmen will consider it safe to operate with lower money balances than they would otherwise. They will expect to be able to obtain a larger portion of the money they will later require, through credit at the time. Consequently, they will invest more fully, either in the purchase of physical assets or in the purchase of securities. And since those who receive this money will tend to behave in the same way, what occurs is an increase in the total volume of spending, lending, and trading of all kinds in relation to the quantity of money; that is, there is an increase in the velocity of money.

On the other hand, in a deflationary period, when the quantity of money is falling and credit is virtually unobtainable, businessmen find it necessary to hold relatively large money balances in order to be sure of being able to meet their obligations when they come due. In these conditions, there is a corresponding reduction in the velocity of circulation of money.²⁹

The final avenue that connects changes in the quantity of money and the velocity of circulation of money is by way of the rate of interest. As we know from Chapter 6, the basic determinant of the rate of interest is the rate of profit.³⁰ And as Chapter 16 will show, to this must be added the fact that an expanding quantity of money, in raising total spending and total sales revenues from year to year, raises the nominal rate of profit.³¹ This rise in the nominal rate of profit brings about a rise in the nominal rate of interest. The rate of interest rises because the higher rate of profit permits business borrowers to offer a higher rate of interest, and their mutual competition for loans forces them to do so. Also, insofar as loanable funds are supplied by those who have the alternative of directly investing in business and earning profits, a rise in the rate of profit makes such lenders require a higher rate of interest as the condition of their finding it worthwhile to continue lending.

Here I must briefly digress, because the connection I have just described between the increase in the quantity of money and the rate of interest is the opposite of that which is usually believed to exist. The usual belief is that an increase in the quantity of money entering the loan market reduces the rate of interest. In view of the prevalence of this belief, some further comments on my part are in order.

An increase in the quantity of money can reduce the rate of interest only temporarily. As soon as the new and additional money is borrowed and spent, it begins to raise sales revenues and profit margins, and thus the rate of profit. The rise in the rate of profit then raises the rate of interest. To prevent the rate of interest from rising in the face of the higher rate of profit, an acceleration in the rate of credit expansion would be necessary. The effect of such an acceleration would be a still more rapid rate of increase in the volume of spending and thus in business sales revenues, with the result that profit margins and the rate of profit would rise still higher, which, of course, would operate all the more powerfully to raise the rate of interest. To prevent the rate of interest from rising at this point, an even more rapid rate of credit expansion would be required, which would cause yet a still higher rate of profit, and so on. Thus, the use of credit expansion to prevent the rise in the rate of interest that results from an increase in the quantity of money would quickly entail such enormous rates of increase in the quantity of money as to destroy the monetary system.

For example, starting with a rate of profit of 4 percent and a rate of interest of 3 percent, credit expansion might temporarily reduce the rate of interest to, say, 2.75 percent. But once the new and additional money succeeds in raising sales revenues and profit margins, the rate of profit rises to, say, 4.25 percent. To keep the rate of interest at 2.75 percent in the face of this higher rate of profit, requires more credit expansion than before. If it is forthcoming, then the rate of profit rises perhaps to 4.5 percent, which means that still more credit expansion will be required if the rate of interest is to be held at 2.75 percent. Since the difference between the rate of profit and the rate of interest steadily widens, making borrowing more and more profitable, exponentially increasing amounts of credit expansion would be required to prevent the rate of interest from rising. To avoid rapid destruction of the monetary system, there is no practical alternative but to allow the rate of interest to follow the rate of profit on up as the quantity of money increases. In pattern, the rise in interest rates in the United States over the thirty-five years following World War II is explainable on the basis of a progressively more rapid rate of increase in the quantity of money, taking place in large measure in the form of credit expansion.

The mistaken notion that increases in the quantity of money reduce the rate of interest is largely the result of thinking of the rate of interest as "the price of money" and then applying the principle that increases in supply reduce prices. A more accurate description of the rate of interest than the price of money is *the difference between the money that is borrowed and the money that is repaid*. Thus, for example, one should think of the payment of a 10 percent rate of interest on a one-year loan of a thousand dollars not as a price for the borrowing of the thousand dollars, but as the difference between the eleven hundred dollars that will have to be repaid and the thousand dollars that is borrowed. If one thinks of interest this way, then it is not surprising that interest rates turn out to be higher rather than lower as the consequence of an increasing supply of money. Because to the extent that more money exists and is spent and earned at the time of repayment than at the time of borrowing—which is the necessary consequence of an increasing quantity of money—correspondingly more money is available to be repaid and is thus likely to have to be repaid than would otherwise be the case.

Thus, the effect of a more rapidly increasing quantity of money and volume of spending has been shown to be to raise the rate of interest after temporarily reducing it. As a result, it is possible to return to considering the connection between the increase in the quantity of money and the velocity of circulation of money that exists by way of the rate of interest.

The rise in the nominal rate of interest that results from a more rapid rate of increase in the quantity of money and volume of spending is significant in drawing out of cash holdings sums that it would not pay to invest at lower rates of interest. It does this by decreasing both the size of the principal and the period of time for which it must be invested in order to make lending worthwhile.

For example, at a 2 percent annual rate of interest, it would probably not pay in present conditions to lend \$100,000 for a period as short as a week, because the interest that could be earned would amount only to about \$40. (Two percent of \$100,000 is \$2,000, which, when divided by 50 weeks, equals \$40.) If we assume that the minimum amount of interest that must be earned by a significant-sized business firm merely to cover the book-keeping and related costs of a financial transaction, and thus make it worthwhile entering into, is \$100, then the smallest-sized sum that it pays such a firm to lend out for a period as short as a week is \$250,000, if the annual interest rate is 2 percent. (Two percent of \$250,000 is \$5,000, which, when divided by 50 weeks, equals \$100.) At a 2 percent annual rate of interest, it would not pay to lend a sum as small as \$100,000 for a period of less than two and a half weeks. However, at a 4 percent annual rate

of interest, it pays to lend a sum as small as \$125,000 for a week, and it pays to lend \$100,000 for a period as short as a week and a quarter. At still higher rates of interest, the minimum-sized sum that it pays to lend out for a given short period, such as a week, becomes still smaller, and the minimum period of time for which it pays to lend any given-sized sum, such as \$100,000, shortens further.

Thus, as the rate of interest rises, it becomes profitable to lend out progressively smaller and shorter-term sums. Consequently, these sums are drawn out of cash holdings and into the stream of spending. Since there are always such sums in the possession of various firms, the effect of a rise in interest rates—itsself caused by a more rapid increase in the quantity of money—is to elevate the velocity of money throughout the year. By the same token, of course, a fall in the rate of interest brought about by a reduction in the rate of increase in the quantity of money operates to decrease the velocity of money.

(In order to avoid a possible erroneous inference, I must point out that a reduction in the rate of profit and interest that might result from a higher rate of saving should *not* be presumed to increase the demand for money and thus reduce the velocity of money. This is because, as we saw earlier in this section, the greater availability of savings and thus credit, operates itself to reduce the demand for money. The same observation, of course, applies *mutatis mutandis* to increases in the rate of profit and interest caused by decreases in the rate of saving. In other words, the relationship between the rate of interest and the demand for money applies only insofar as the rate of interest is determined by changes in the quantity of money and volume of spending, not insofar as it is determined by the rate of saving.)

I must also point out that it is of no relevance that the effect of increases in the quantity of money is not only to add to the rate of interest, but also progressively to increase the size of the minimum sum for which it is worthwhile to lend, at least in comparison with what it otherwise would have been. This is because the increase in the minimum-sized sum does not affect the *proportion* of the money supply that it pays to lend for given short periods of time at any given rate of interest. Other things being equal, an economic system with a doubled quantity of money and a doubled minimum-sized sum for which lending is worthwhile will tend to have the same proportion of its money supply available for short-term lending at any given interest rate as an economic system with the original quantity of money. If, however, its interest rate is higher, because of a more rapid rate of increase in the quantity of money, it will tend to lend out a larger proportion of its money supply. Therefore, its velocity of circulation will be higher.)

Thus, in the four ways I have explained, increases in

the quantity of money raise the velocity of money, and decreases in the quantity of money decrease it.

Let us turn to the historical statistics of the money supply and its velocity of circulation for verification of this relationship. These statistics are shown in Table 12–1.

In viewing the statistics, of course, we should not expect the relationship to hold with immediacy. Very importantly, the influence of earlier changes in the quantity of money can continue to be felt for a time after the direction of change in the quantity of money has been reversed. Thus, a period of inflation which begins after a sustained period of deflation, and in which people's expectations continue to be influenced by their experience of deflation, will not be accompanied by an immediate rise in the velocity of circulation of money. On the contrary, it will be accompanied initially by a *fall* in the velocity of circulation of money. This will be the case in such an environment because people will want to take the opportunity of an increased availability of money to build up their cash reserves, as a precaution against renewed deflation. Only after a period of time has gone by, and the memory of the deflation has given way to the continuing experience of inflation, will the demand for money start to fall and velocity to rise.

By the same token, after a period of sustained inflation, the immediate effect of a slowdown in the rate of increase in the quantity of money may well be a further rise in the velocity of circulation of money. This will be the case if people believe that the inflation will soon resume on as great or greater a scale than before and hence become willing temporarily to operate with even lower cash holdings than before.

It is also possible that velocity may drop in the face of an undiminished rate of increase in the supply of money, indeed, even in the face of an accelerated rate of increase in the supply of money. This result can occur if the realization of people's expectations concerning inflation presupposes a more rapid rate of increase in the quantity of money than actually takes place. In such circumstances, they will have reduced their demand for money unduly in the light of the facts. Thus, they will need to increase their demand for money.

The data in Table 12–1 can be broken down into four main periods: 1914–29, 1929–45, 1945–82, and 1982 to the present. The first of these periods runs from just prior to the outbreak of World War I in Europe to the start of the Great Depression. The second runs from the start of the Great Depression to the end of World War II; the third, from the end of World War II to the most severe postwar recession; the fourth spans the subsequent recent years.

Since reliable GDP/GNP statistics are unavailable prior to 1929, it is not possible to compute values for

Table 12-1
 Money Supply, Consumer Demand (GNP/GDP), and Velocity of Circulation
 in the United States, Selected Years, 1914-1993

Year	Money Supply (in billions)	Consumer Demand (GNP/GDP in billions)	Velocity
1914 Je.	\$11.5	N. A.	
1920 Je.	23.7	N. A.	
1921 Je.	20.8	N. A.	
1925 Je.	24.9	N. A.	
1929 Dec.	26.4	\$103.1	3.9
1933 Je.	19.2	55.6	2.9
1939	36.2	90.5	2.5
1945	102.3	211.9	2.1
1950	116.2	284.8	2.5
1955	135.2	398.0	2.9
1960	144.2	503.7	3.5
1965	171.3	681.2	4.0
1970	219.6	976.4	4.4
1975	294.8	1506.0	5.1
1980	414.9	2633.1	6.3
1981	441.9	2957.8	6.7
1982	479.9	3069.3	6.4
1983	527.1	3405.7	6.5
1984	558.5	3765.0	6.7
1985	620.1	4014.9	6.5
1986	725.4	4240.3	5.8
1987	750.8	4526.7	6.0
1988	787.8	4861.8	6.2
1989	794.1*	5250.8	6.6
1990	826.1	5522.2	6.7
1991	899.3	5677.5	6.3
1992	1026.6	5945.7	5.8
1993	1128.4	6343.3	5.6

*Data are for GDP starting with 1989.

C.: Board of Governors of the Federal Reserve System, 1943), p. 34; idem, *Banking and Monetary Statistics 1941-1970* (1976), pp. 5, 17-19; idem, *Annual Statistical Digest 1971-1975* (1976), p. 49; idem, *Federal Reserve Bulletin*, December 1981, pp. A13, A52; February and November 1985, pp. A13, A51; October 1986, pp. A13, A51; March 1989, pp. A13, A53; April 1992, pp. A14, A51; October 1994 pp. A14, A51. *National Income and Product Accounts of the United States 1929-1965* (Washington, D.C.: U.S. Department of Commerce, 1966), pp. 2-3.; *Survey of Current Business*, July 1972, p. 7. From 1939 on, money supply data are for December of each year.

velocity in the first period, as we are able to do for all the years from 1929 on simply by dividing the money supply into the GDP or GNP. Nevertheless, we can infer a rise in velocity over the course of the 1920s from all the reports depicting the era as a period of great financial boom. To qualify for such a description, it seems certain that the increase in spending over the period had to exceed the 27 percent cumulative increase in the money supply between June of 1921 (the reporting date following the reduction in the money supply in the depression of that year) and December of 1929. For that increase works out to be only slightly more than 2.8 percent per year on a compound annual basis.

Velocity rose in the twenties on the foundation of a combination of the sharply increased money supply of World War I and an aggressively easy money policy on the part of the Federal Reserve System from June of 1921 to the end of 1925. From June of 1921 to June of 1925, the money supply increased at a compound annual rate of slightly more than 4.6 percent. Also very important in explaining the rise in velocity in the 1920s was the widely held conviction that the Federal Reserve System, by virtue of its ability to increase the supply of currency and member-bank reserves, had the power to prevent depressions and achieve permanent prosperity. In this environment, the demand for money fell and business firms became relatively illiquid.

The far more modest rate of increase in the quantity of money in the late 1920s presaged a fall in velocity. From June of 1925 to June of 1929, the money supply increased at a compound annual rate of approximately only 1.1 percent.³² The fall in velocity began by the end of 1929, and intensified thereafter. The disastrous monetary contraction of the period 1929–1933 can be explained on the basis, first, of an undue increase in the quantity of money, coupled with the conviction that the Federal Reserve System would prevent any future depression. These factors reduced the demand for money and raised the velocity of money to levels that could not be sustained in the absence of a continued rapid increase in the quantity of money. This continued rapid increase in the money supply did not occur. When, as a result, the demand for money finally increased and velocity correspondingly fell, the effect was reduced spending, hence reduced revenues and incomes, and thus a decreased ability to repay debts.

This last, in turn, resulted in bank failures and an actual decrease in the quantity of money, as fiduciary media were wiped out under the fractional-reserve monetary system of the time. The decrease in the quantity of money caused a further decrease in spending and, concomitantly, a further decrease in revenues and incomes, and thus an even greater reduction in the ability to repay

debt, with the result of still more bank failures and a still greater reduction in the quantity of money. The cumulative fall in the money supply between 1929 and 1933 was approximately 27 percent! (This put the money supply in 1933 below where it had been in 1921.)

In the face of a declining quantity of money, velocity fell still further, as it became urgently necessary for business firms to raise cash to be sure of being able to pay their debts and as the expectation grew that investments made in the present could not only be made cheaper in the future, once wage rates and other costs fell, but, if made in the present, would incur an actual financial loss. The prospect of falling prices accompanied by the prospect of being unemployed in the future led consumers, too, to retrench on current spending. In the face of lack of profitable investment opportunities caused by declining sales revenues, their retrenchment in consumption spending largely meant a reduction in spending as such. Because of these factors, velocity fell from 1929 to 1933—from 3.9 to 2.9.

Our table shows, of course, that the velocity of circulation continued to fall from 1933 to 1945, despite very major increases in the money supply from 1933 on. But this is not difficult to explain. The disastrous deflation of the early thirties, in which, as just noted, the money supply fell by more than 25 percent, in which credit was unobtainable by virtually all but the strongest enterprises, in which thousands upon thousands of firms went bankrupt, was an experience that guaranteed a very high degree of financial conservatism for many years to come. As a result, even though the money supply began to increase again after 1933, funds were used to an uncommon degree to build liquidity; that is, firms chose to operate with unusually large money balances. They acted out of fear of the recurrence of deflation. This explains the continuing fall in velocity during the remainder of the thirties.

In World War II, velocity fell because of wartime government controls that limited demand. During the war, the government imposed all-round price and wage controls and instituted a system of consumer rationing. This necessarily limited the amount of spending in the economic system, because no one could spend a sum larger than the controlled prices times the limited quantities of goods available to him. At the same time, of course, the money supply was sharply increased. The combination of a governmentally limited demand and a sharply rising money supply mathematically necessitated a falling velocity of circulation.

By the early postwar years, the memory of the Great Depression and the fear of its recurrence had substantially receded, and from this period on the velocity of circulation began to rise. As in the late twenties, the years

1955 to 1960 experienced only a modest rate of increase in the quantity of money—approximately only 1.3 percent per annum. Indeed, in the early sixties, there was even a stock market crash—the most severe since 1929. But this time, the government saw to it that the quantity of money did not decrease but increased more rapidly. And thus by 1965 we see velocity reaching levels in excess of the 1929 peak.

From 1960 on, the rate of increase in the quantity of money accelerated in every five year period until 1985. From 1960 to 1965, the five-year rate of increase was 18.8 percent; from 1965 to 1970, 28.3 percent; from 1970 to 1975, 34.2 percent; from 1975 to 1980, 40.7 percent; and from 1980 to 1985, 51 percent. Not surprisingly, the velocity of circulation of money went on increasing over most of this period. It reached a peak of 6.7 in 1981.

The increase in the velocity of circulation from the end of World War II until 1981 is exactly what we would expect on the basis of our theoretical knowledge. It was an effect of the increase in the quantity of money that had been going on since 1933 and which tended to accelerate over time, with no sign of major interruption. By the end of the 1970s the demand for money in the United States had fallen to a point where it reflected a growing expectation that the country might soon experience a Latin-American style inflation.

This expectation did not materialize, however. And since 1982, velocity has receded from its 1981 peak. This result, too, is what we should expect on the basis of our theoretical knowledge. For in 1980 and 1981, what occurred for the first time in the post-World War II era was precisely *a major interruption in the accelerating rate of increase in the quantity of money*. In those two years, the Federal Reserve System made a sharply reduced rate of growth in the money supply its highest priority. It supplied additional reserves to banks only at a ruinously high discount rate of 16 percent. People who had been counting on a rapidly accelerating increase in the money supply—who had further overextended themselves when such an increase failed to materialize, in the belief that it very soon would, in conformity with the pattern established in all the previous recessions experienced since the end of World War II—were caught short and had to scramble for funds.

In response to their desperate demand for funds, the government brought about an increase in the money supply of 8.5 percent in 1982 and 9.8 percent in 1983 (following an increase of 6 percent in 1980 and 6.5 percent in 1981), but only at interest rates so high as to make most borrowing unprofitable and only in order to prevent what otherwise would certainly have been the start of a major depression. Even so, the consequence of the change in government policy was the most serious

recession—the first actual depression, according to some observers—since the 1930s. A further consequence was that since that time the U.S. government has been viewed as being unwilling to allow a continuous acceleration in the rate of increase in the quantity of money. The effect of this has been an increase in the demand for dollars and a consequent tendency toward a decline in the velocity of circulation of dollars. (In the early 1980s, a major factor cushioning the effects of the increase in the demand for money for holding was the rapid increase in so-called money-market-mutual-fund accounts. These are interest-bearing savings accounts that closely resemble checking accounts in that their holders have the right to write up to three checks per month against them. Between December of 1978 and December of 1982, these accounts grew from a little over \$10 billion to \$230 billion.³³)

Ironically, the effect of the increase in the demand for money inaugurated by the government's policy of restricting the growth in the supply of money earlier in the decade was to enable the government to resort to a renewed acceleration of the increase in the supply of money in 1985 and 1986, with rates of increase of in those years of 11.1 percent and 16.9 percent, respectively.

Given the prevailing still relatively low state of demand for money that has resulted from decades of inflation, such rapid rates of increase in the money supply are necessary to prevent the greater demand for money corresponding to moderate increases in the money supply from resulting in a decline in total spending in the economic system and thus launching a depression. This conclusion is confirmed by subsequent events. In the remainder of the decade the rate of increase in the money supply was sharply reduced: in 1987 it was 3.4 percent; in 1988, 5 percent; in 1989, 1 percent; in 1990, 4 percent. The five-year rate of increase in the money supply between 1985 and 1990 ended up as 33 percent—the first five-year increase since 1960 that was less than the previous five-year increase. Not surprisingly, in late 1990, and in 1991 and 1992, the economic system seemed poised for a major depression.

In an effort to overcome the slide toward depression, in 1991 the increase in the quantity of money was stepped up to almost 9 percent. In 1992, it was in excess of 14 percent, and in 1993, more than 10 percent. Because these increases in the quantity of money took place in an environment of largely deflationary psychology, the result was a substantial fall in the velocity of circulation of money over the years 1991–93, namely, from 6.7 in 1990 to 5.6 in 1993, as shown in Table 12–1. Finally, in late 1993, because of the sharply increased quantity of money and the consequent ability of sales revenues and profits

to increase from year to year, along with the rise in liquidity constituted by the lower velocity of circulation, the widespread fears of impending depression gave way. In the current year, 1994, there are growing fears of a resumption of more rapidly rising prices. The Federal Reserve System shares these fears, and in the present year has once again sharply reduced the rate of increase in the quantity of money—to a little over 2 percent on an annual basis (i.e., from \$1,128.4 billion at the end of December 1993, to \$1,149.4 billion in mid-October of 1994).³⁴

What is certain is that if the rapid rates of increase in the money supply that prevailed from 1991 through 1993 were to be continued, the demand for money would once again sharply decline, in which case rapid increases in the quantity of money would be joined by a substantial rise in the velocity of circulation of money, with the result that very rapid increases in spending would ensue. On the other hand, it is no less certain that if the present, modest rate of increase in the money supply were to remain in force, a major increase in the demand for money would take place, such as began in 1990. This would result in a large-scale monetary contraction—that is, a major deflation/depression. To put it mildly, the present monetary situation is highly unstable, possessing as it does the potential both for major inflation and for major deflation. Under present monetary conditions, the economic system is poised between both dangers, with the government undertaking to prevent the one only by means of unleashing the other and then hoping to be able to change course quickly enough to overcome the momentarily greater danger by enlarging and setting against it the momentarily smaller danger.

It should never be forgotten that this deadly alternative would not exist if the policy of inflation had not been resorted to in the first place. Even now, I do not think that the alternative is inescapable, and in Chapter 19 I will present a solution for stopping inflation without precipitating a depression—a solution that is fully consistent both with a sharp increase in the demand for money and consequent major decline in the velocity of circulation, and yet, at the same time, with no decrease, indeed, an increase, in the volume spending in the economic system expressed in dollars.³⁵ As I will also show in Chapter 19, in the absence of once and for all ending the policy of inflation, the problem must remain substantial, as a minimum. More likely, it will grow worse.³⁶

4. The Demand for Money: A Critique of the “Balance of Payments” Doctrine

Knowledge of the demand for money sheds light on the questions of the “balance of trade” and the “balance

of payments.” These are matters in connection with which arguments have been advanced, and generally accepted, to the effect that the vital self-interest of countries requires restrictions on the freedom of international trade. Worse, on the foundation of the belief that countries benefit from an excess of exports over imports, or of receipts from abroad over outlays to abroad, and are harmed by the opposite type of excess, the implication arises, in the clearest possible terms, that the self-interests of countries are necessarily opposed to one another. For, in the nature of the case, it is impossible for a country to have an excess of exports over imports, or receipts from abroad over outlays to abroad, without other countries having an equivalent excess of the opposite kind. Thus, each country, in pursuing what is believed to be its economic self-interest is perceived as bent at the same time on a policy that causes harm to other countries. In this way, the doctrine of the balance of trade or balance of payments serves as a leading cause of international conflict and, ultimately, of war. Few things, therefore, can contribute more to world peace than its overthrow. In accordance with this objective, I will first present the substance of the doctrine and then turn to a critique of it.

The balance of trade is the difference between the money received by the citizens of a country in exchange for exports of goods to foreign countries and the money expended by the citizens of that country in exchange for imports of goods from foreign countries. The balance of payments is an essentially similar, but more comprehensive concept. It is the difference between the total of a country’s receipts from abroad and the total of its outlays to abroad. Under the heading of receipts are included not only receipts from the export of goods, but also receipts from the sale of services to foreigners, such as shipping, insurance, and the hosting of tourists. Dividends and interest received from abroad, the proceeds from the sale of securities, such as stocks and bonds, to abroad, and the proceeds of borrowings and the repayment of debts from abroad are also included. By the same token, outlays to abroad include, along with outlays for imports, the purchase of services from foreigners, dividends and interest paid to them, remissions of gifts by individuals to abroad, government foreign aid, the purchase of securities from abroad, and the granting of loans and repayment of debts to abroad.

For historical reasons that will be made clear shortly, an excess of exports over imports is mistakenly called a favorable balance of trade, while an excess of imports over exports is mistakenly called an unfavorable balance of trade. Similarly, an excess of the total of all categories of receipts from abroad over the total of all categories of outlays to abroad is mistakenly called a favorable balance of payments, while an excess of the total of all

categories of outlays to abroad over the total of all categories of receipts from abroad is mistakenly called an unfavorable balance of payments.

From the perspective of the history of economic thought, the concepts of the balance of trade and the balance of payments can be taken as interchangeable. This is because when the concept of the balance of trade became prominent, with the writings of the Mercantilists in the seventeenth and eighteenth centuries, commercial dealings with foreign countries were essentially limited to imports and exports. There was as yet no significant international capital market, and the international exchange of services was also not significant.

In order to understand the importance attached to these concepts historically, it is necessary to consider the context in which the Mercantilists wrote and the ideas they advanced in connection with these concepts. The Mercantilists lived in a time when gold and silver constituted the money of all countries. Countries which did not possess gold and silver mines, which was the situation of most of the European nations of the period, could obtain an additional supply of money only from abroad. Insofar as the money was to be obtained by trade, an excess of exports over imports was the only possible means.

Obtaining an additional supply of money in a country was originally thought to be important as a means of financing future foreign wars. It was thought that the additional money would be available for taxation when it became necessary for the king to finance foreign military ventures, which would require the spending of precious metals abroad, and that it was possible and necessary to heap up sufficient "treasure" in a country to cover all or at least a substantial part of the cost of such ventures. Increasingly, however, a wider economic perspective entered in. It came to be held that a growing quantity of money obtained from an excess of exports over imports would provide an economic stimulus to production and employment in the country by virtue of increasing the volume of spending, and could lower interest rates by providing a larger quantity of money for lending. For all of these reasons, an excess of exports over imports was held to represent a "favorable" balance of trade.

In exactly the same way, an excess of imports over exports was perceived as reducing the quantity of money in a country. This, it was thought, not only impaired the ability of the country to finance future foreign wars, but reduced spending, production, and employment in the country, and raised its interest rates as well, which further contributed to its economic woes. For all of these reasons, an excess of imports over exports was called unfavorable.

On the Mercantilist view of things, in the absence of

government intervention to secure a favorable balance, the balance of trade (payments) was determined on an essentially accidental basis. It was the fortuitous outcome of the unrelated actions of everyone who happened to sell to abroad or buy from abroad. Any individual action which increased exports was thought to improve the balance of trade correspondingly. Any individual action which increased imports was thought to harm the balance of trade correspondingly. On the mercantilist view of things, imports had the potential of completely draining a country of its money supply—if, for a period of years purchases from abroad happened to exceed receipts from abroad by a wide enough margin. Indeed, the only justification of imports was thought to be either their absolute necessity in meeting important needs that otherwise could not be supplied or in bringing about subsequent exports that would constitute an improvement in the overall balance of trade. (The latter was thought to be the case insofar as imports were in the form of raw materials or equipment advantageous to the production of subsequent exports.)

The element of "heaping up treasure" to finance future foreign wars is no longer prominent. Among other things, it was shown to be incapable of making any significant contribution to the end sought, since the size of money holdings is always quite modest relative to the volume of expenditures which must be made. The actual source of wartime military expenditures abroad is always, overwhelmingly, the proceeds of current exports and borrowings from abroad. The plans of kings and emperors for accumulating precious metals within the borders of their countries turned out, on calculation, to be sufficient for supporting the war expenses of no more than a few weeks or months.

But apart from this element, Mercantilism has a very contemporary ring to it. It bears a close similarity to the ideas of Keynes and his followers in its concern with finding a source of economic "stimulus," and in its fear that in the absence of such stimulus, the economic system must languish in unemployment and poverty. Its views on the ability of a larger quantity of money to reduce interest rates are also practically indistinguishable from those of Keynes.

Mercantilism's treatment of the balance of trade (payments) as being the fortuitous outcome of the unrelated actions of individuals is also shared by most contemporary writers and commentators on the subject. It is manifested in such attitudes as that the American balance of payments is unfavorable because Americans are buying too much specifically from the Japanese, or, even more specifically, too many automobiles and electronics products from the Japanese. At other times, the specific sources of the trade or payments imbalance of the United

States has been held to be such things as the purchase of imported wines from France, tourism by Americans in foreign countries, American lending abroad, the stationing of American soldiers abroad, and the giving of foreign aid.

The presumption is that if each or any of these outlays was not present, total outlays would be equivalently reduced and thus the difference between outlays and receipts correspondingly improved. On the basis of the view that the problem of an unfavorable balance originates in this way, the remedy that appears to follow is the imposition of restrictions or prohibitions on the particular dealings in question. Thus, depending on what is being singled out at the moment, Americans have variously been urged to buy less French wine, take their vacations at home, reduce their lending abroad, and, most recently, not to buy Japanese products. Needless to say, corresponding laws and regulations have been proposed and enacted.

Of course, by the same token, any particular source of receipts from abroad is capable of being singled out for praise, on the grounds of its corresponding contribution to the country's balance of trade or payments. For example, in the 1960s, the members of a prominent rock 'n roll group were made Members of the Order of the British Empire on the basis of their alleged contribution to Britain's balance of payments through their receipt of large concert fees and recording royalties earned in the United States and Continental Europe. Of course, an obvious implication of the view that any given receipt from abroad represents a corresponding improvement in a country's trade or payments balance is the subsidization of exports. Export subsidies—the taxpayers' loss—are thought to be the basis of a gain to the nation.

The Balance of Payments Doctrine and Fiat Money

Now the first thing which should be realized about the concepts of the balance of trade and the balance of payments is that whatever plausibility they may have had in the days when a country's money supply depended on gold obtained from abroad, they no longer possess even that plausibility. Indeed, it is highly ironic, but nowadays expenditures for the importation of *gold itself* are believed to add to a country's balance of payments deficit. (For example, an important motivation in the decision of the U.S. Congress to order the minting of a new American gold coin a few years ago was the belief that it would help the United States' balance of payments to some extent by giving American citizens an alternative to buying imported gold coins, such as the Canadian Maple Leaf and the South African Krugerrand.)

Over two centuries ago, Adam Smith wrote, for reasons that will soon become apparent, "Upon every ac-

count, therefore, the attention of government never was so unnecessarily employed, as when directed to watch over the preservation or increase of the quantity of money in any country."³⁷ When one realizes that today, the whole concern over the balance of trade and the balance of payments is over an alleged outflow of *irredeemable paper money*, this concern must be judged utterly absurd.

Even if it were the case that an unfavorable balance of payments meant a corresponding reduction in the quantity of money in a country, absolutely nothing could be more easily replaced than a loss of fiat money. All that is required is additional paper and ink, and not even that—just some additional credit entries on the ledgers of the banks. Indeed, to some extent every year there is an outflow of currency from the United States. For there are people living in many foreign countries whose currencies depreciate far more rapidly than the dollar, and who therefore prefer to have holdings of dollars rather than holdings of their own currencies—who want to have dollars in safety deposit boxes or even hidden under their mattresses. Indeed, there is an important demand almost everywhere for dollars to be used as an international currency, that is, in financing trade among most foreign countries. To that extent, there is a demand for dollars in the form of checking deposits as well. But these phenomena do not cause any actual reduction in the supply of money in the United States. They merely cause a somewhat lesser rate of increase. That is, the quantity of money in circulation in the United States does not increase by the full magnitude of the increase in the supply of dollars, but by an amount which is less to the extent that part of the increase is taken by foreigners, in exchange for goods and services they supply us. It is difficult to see how there is anything at all that is "unfavorable about this." It achieves the equivalent of a lesser degree of inflation in the United States and provides the American economy with real goods and services in exchange for intrinsically worthless pieces of paper.

But what is truly ironic is that the far greater part of what is recorded as an unfavorable balance of payments does not even represent any actual outflow of money—not even fiat money! On the contrary, it is constituted by *an increase in short-term foreign lending* to the citizens of the country, or to its government. For example, when foreigners take the dollars they have earned in selling goods or services in the United States, or simply go out and exchange their own money for dollars, and then deposit the proceeds in American banks or their overseas branches, which then remit them to the United States, or when foreigners buy U.S. treasury bills or commercial paper—that *increase in short-term liabilities to foreigners is said to constitute an unfavorable balance of payments to the United States!*

It is no less difficult to understand what is unfavorable about this than about an outflow of fiat currency. The dollars that the foreigners deposit in banks here or abroad are lent out and spent in the United States, and the same is certainly true of the funds they use to purchase U.S. treasury bills or commercial paper.³⁸ Indeed, such short-term foreign lending should be regarded as an indication of the *strength* of a country's economic system, in that it shows that foreigners consider the country to be a worthwhile place to invest their money. The same point, of course, applies even more strongly to intermediate and long-term foreign investment.

Foreign lending and investment contribute to domestic capital formation and thus, as later chapters of this book will show, to the rise in the productivity of labor and real wages—developments that are as favorable to a country as can be imagined. And, in passing, it should be realized that, at least until recently, foreign lending and investment in this country have helped greatly to alleviate the drain of capital funds that would otherwise have resulted from our massive government budget deficits. They have also prevented the pressure that would then exist to finance those deficits through the more rapid creation of money. There is nothing “unfavorable” about this.

Obviously, the receipt of funds in connection with foreign short-term lending and investing should very definitely be counted among a country's international receipts. Its omission creates the appearance of an imbalance in a country's international accounts when in fact there is none. And it makes what in reality is a perfectly favorable development appear unfavorable. To this extent, the doctrine of the balance of payments represents a fiction as well as an absurdity.

This leads to a wider problem in the concept of the balance of trade and payments—namely, that it is not seen that the various items in the accounts are not independent, but rather are mutually interconnected. For example, the so-called unfavorable balance of trade (the excess of imports over exports) that the United States has experienced in recent years is precisely the result of the excess of receipts by the United States over outlays in the vital area of lending and investing.

This latter excess has been largely due to the fact that in the early and mid-1980s the United States came to be considered the outstanding country in which to invest. This was the result of an apparent determination on the part of its government to restrain the growth in the money supply, to provide a more favorable tax treatment of profits, and to reduce the extent of its own interference in the economic system. All this was coupled with the existence of historically very high rates of interest.

As the result of a massive inflow of foreign funds seeking dollars for investment purposes, the exchange value of the dollar rose sharply in terms of other currencies. This rise in the foreign-exchange value of the dollar, in turn, made American goods correspondingly more expensive for foreigners to buy, inasmuch as foreigners first had to buy more expensive dollars in order to buy American goods, and, by the same token, made foreign goods correspondingly cheaper for Americans to buy, inasmuch as a dollar now bought more of foreign currencies and thus more of foreign goods. Thus, the foreign investment resulted in an excess of imports over exports. It provided both the financial means of purchasing imports without making corresponding exports and, at the same time, a financial incentive, in the form of a high foreign-exchange value of the dollar, leading the economic system to do precisely that.

Indeed, it is in the very nature of foreign investment that it be accompanied by a so-called unfavorable balance of trade in the country receiving the investment. What the foreign investment contributes is *physical wealth* from abroad. In the country receiving the wealth, this means an importation of goods without a corresponding exportation of goods. Only in this way can there be a net inflow of wealth.

Perhaps the clearest illustration of how foreign investment means an “unfavorable” balance of trade can be found in the economic development of a wilderness area. Thus, imagine, for example, that there is a stretch of coastline somewhere that contains oil deposits. To exploit the oil deposits, wells must be drilled, a refinery and storage tanks constructed, piers and warehouses built, and so forth. All of this must come from outside the area—from abroad. Its coming represents a great investment. But it is simply impossible that there can be corresponding exports while the area is in process of development. Its development is possible only so long as it is able to obtain funds with which to pay for imports of all kinds *without as yet having to make corresponding exports*. Yet, incredibly, while the area's development is going on, its balance of trade is called “unfavorable,” because it imports more than it exports. What would allegedly not be unfavorable is if the area did not receive the imports that make its development possible.

The same principles, of course—the same actual favorableness of the “unfavorable” balance of trade—apply to a great nation that already is very highly developed, but is undergoing still further development. They also apply to a case in which the influx of wealth from abroad serves to offset the consumption of capital at home by a voracious government.

Such an excess of imports over exports does not in the least cause unemployment. And the truth of this state-

ment is confirmed by the fact that precisely in the period of its massive trade deficits, the unemployment rate in the United States has been among the lowest of any major nation. As should already be clear, the purchase of the imports does not represent any significant carrying out of money from the United States or any reduction in total, overall spending for goods and services in the United States. On the contrary, the imports represent new and additional wealth brought into the United States, where they are added to the supply of domestically produced goods and made available for purchase by the same total expenditure of money that would otherwise take place. In other words, the American public obtains more for its money. The real wealth in the economic system is increased and the rise in prices is correspondingly retarded. (The reduction in exports that foreign investment in the country achieves by means of raising the foreign-exchange value of the country's money contributes to the same result. For a portion of the country's output which otherwise would have been exported is made available for purchase domestically instead.)

The following example shows the actual nature of what takes place. Thus, imagine that there is a German business firm that exchanges two million marks for one million dollars. The German firm places these million dollars in a bank, in a time deposit. The bank lends them out to an American business firm, which now expends them in the United States in the purchase of such things as plant and equipment, materials, and labor services. The firm's employees, in turn, spend their wages in buying various consumers' goods from other American businesses. Observe. There is no reduction in the number of dollars in the American economy, nor any reduction in spending for goods and services in the American economy. All that is different in the American economy is that the seller of the million dollars to the German firm now has two million marks and thus the means of importing two million marks' worth of goods into the American economy. In other words, there is the same money and spending as before, but more goods in the American economic system for the same volume of aggregate spending to buy.

Let us take another example. A Japanese automobile company sends a shipload of cars to the United States, for which it is paid a sum of dollars. It must use most of these dollars to buy yen, in order to have the funds to maintain its operations in Japan. Some of the dollars, however, it saves and deposits in American banks or uses to buy American securities. These dollars are spent in the United States, just as in the previous example. Most of the dollars that are exchanged for yen will be used by Japanese to import from the United States. The rest of the dollars are used to invest in the United States and, of

course, are expended here in the process. Again, the full supply of dollars turned over to the foreigners comes back as purchases within the United States. But what occurs is that *the supply of goods in the United States is correspondingly larger*: it is larger to the extent that the United States' import of automobiles exceeds its export of goods purchased with the dollars coming into the hands of foreigners. This last is the result insofar as the foreigners invest their dollars in the United States rather than import from it.

The rise in the foreign exchange value of a country's money that foreign investment in the country causes not only does not cause unemployment in that country, but actually tends to be accompanied by *less* unemployment. This is because the demand for labor is made overwhelmingly out of capital, which foreign investment increases. Foreign investment enlarges the capital funds in the possession of the average business firm in the country and thus puts it in a better position to employ labor. True enough, the rise in the foreign-exchange value of the country's money encourages imports and reduces exports, but it does not reduce the quantity of money or volume of spending in the country and actually tends to increase the volume of spending for labor and capital goods. What it does, to say it yet again, is increase the overall supply of goods in the country.

It is perfectly true that there are individual industries, such as automobiles and steel in the United States today, which are presently suffering large-scale unemployment because of their inability to meet foreign competition. If foreign competition were prohibited, these industries would suffer less unemployment. But unemployment in the rest of the economic system would grow more than correspondingly, or else wage rates in the rest of the economic system would have to fall. This is because the purchase even of the same quantity of domestically produced automobiles and steel as are presently purchased, under foreign competition, would require the expenditure of substantially larger sums of money at the higher prices that would then prevail. This would imply a reduction in expenditure for the output of the rest of the economic system, given the supply of money and the volume of aggregate spending in the economy. The reduction in expenditures elsewhere in the economic system would be all the greater, to the extent that the quantity of domestically produced automobiles and steel purchased at the higher prices was increased. In addition, the loss of foreign investment would operate to reduce the aggregate demand for labor in the United States. Thus, the additional employment offered by the auto and steel industries would be more than offset by the reduction in employment that the rest of the economic system could offer.

Thus, in sum, an end to the so-called unfavorable

balance of trade would come about as the result of the end of net foreign investment in the United States. It would be accompanied by a spurt in the level of prices, reflecting a reduced supply of goods available for sale. It would also mean that the full burden of the federal budget deficits would fall on the American economy. And it would tend to be accompanied by a higher overall rate of unemployment, not a lower one. Unfortunately, government policies in the United States may well have the effect of ending net foreign investment and thus of producing these highly undesirable consequences.

It is worth pointing out, as a final irony in the misconceptions surrounding the balance of payments and the balance of trade, that by any rational standard what is called a favorable balance of trade can in fact be fully as much unfavorable as an allegedly unfavorable one is favorable. A country that desires to achieve an excess of exports over imports has only to give money to its prospective customers, and they will import more and it will export more. This is exactly the kind of "favorable" balance of trade achieved by foreign aid. It can be duplicated on a small scale by any businessman who is willing to employ a doorman to give money to passersby on the condition that they spend the money in his shop.

The Balance of Payments Doctrine Under an International Precious Metal Standard

It is necessary to give some consideration to the balance-of-trade and balance-of-payments doctrines under an international gold standard. For in one form or another, this was the monetary system of the world until fairly recently, and could well become so once again. It will be seen that here, too, one of the most important things to keep in mind is that the individual items in the balance are not independent and fortuitous, but mutually interconnected.

Under a system in which the money supply of the various countries consisted of the precious metals, all of the beneficial effects of foreign investment explained above would be equally present. Instead of resulting in a higher foreign exchange value of a country's money, however, foreign investment would operate to enlarge the recipient country's money supply somewhat and, in so doing, make its prices higher than they would otherwise have been and thereby encourage imports and discourage exports. The resulting excess of imports over exports would once again be the physical mechanism by which foreign capital was transmitted to the country. And once again, the effect on overall employment would be positive, not negative, because of the greater availability of capital funds in the country.

In addition, further important principles would apply. A tendency would exist for the money supply of each

individual country to follow the country's proportion of the world's production and trade. A country whose economy represented 10 percent of the world's economy would tend to possess 10 percent of the world's money supply within its borders. A country whose economy represented 20 percent of the world's economy would tend to possess 20 percent of the world's money supply within its borders, and so on. This is because money is demanded for making purchases and paying bills. The larger the relative size of a country's economy, the larger would tend to be its relative sales revenues and purchases to the same extent, and thus the larger its relative need for and ability to obtain holdings of money.

In such conditions, if the world supply of precious metals grew at a rate of, say, 2 percent per year, a country whose economy grew at the same rate as the world's economy and which, therefore, continued to constitute the same proportion of the world's economy, would tend to experience a 2 percent annual rate of increase in its money supply. The principle is that the money supply of an individual country would grow at the same rate as the world's money supply if its economy grew at the same rate as world's economy. By the same token, countries whose economies grew at a faster rate than the world's economy and whose relative share of the world's economy, therefore, tended to increase, would experience a rate of growth in their money supplies more rapid than the rate growth in the world's money supply. At the same time, those countries whose economies grew at a rate slower than that of the world's economy would experience below-average rates of increase in their money supplies, or even decreases in their money supplies.

These facts have an obvious bearing on the balance of payments positions of the various countries. Other things being equal, the more rapidly growing is the economy of a country relative to that of the rest of the world, the greater will tend to be its importation or the less will tend to be its exportation of the precious metals. This is because it will require within its borders a correspondingly larger proportion of the world's supply of precious metals. Thus, the more "favorable" or the less "unfavorable" will tend to be its balance of payments. Conversely, the less rapidly growing is the economy of a country relative to that of the rest of the world, the less will tend to be its importation or the greater will tend to be its exportation of the precious metals—that is, the less "favorable" or the more "unfavorable" will tend to be its balance of payments.

To take a major historical illustration, the rapid growth of the British economy relative to that of the rest of the world in the eighteenth and nineteenth centuries operated to produce a rising demand for money in Great Britain and a "favorable" balance of trade for Great Britain. At

the same time, the stagnation and thus the relative decline of the economies of countries like India and China operated to produce a decline in the demand for money in those countries and an outflow of the precious metals.

The relative rates of growth in the economies of the different countries is not the only principle governing their balance-of-payments positions under a world precious metals standard. An equally important factor is the extent to which a country possesses or lacks precious-metal mines. Those countries in which the precious metals are mined in substantial quantities would regularly experience an “unfavorable” balance of payments. They would regularly export precious metals in exchange for the importation of ordinary commodities. By the same token, the countries in which there was little or no mining of the precious metals would regularly experience a “favorable” balance of payments: they would import precious metals in exchange for ordinary commodities.

These results would take place because of differences in the buying power of the precious metals between the two types of countries. In the countries in which the precious metals were mined, the supply of money would tend to be unduly high, and thus prices would tend to be higher than elsewhere in the world. This would make the importation of goods more attractive, since imports would be relatively cheap, and, at the same time, the exportation of goods other than the precious metals, less attractive, since such exports would be relatively more expensive than the goods people could buy elsewhere. An outstanding historical illustration is provided by the discovery of the California gold fields in 1848. The great local abundance of gold relative to ordinary commodities resulted in such phenomena as the price of a single egg being as high as a dollar for a time (a *gold* dollar of one-twentieth of an ounce of gold, which today represents the value of a substantial number of paper dollars). Thus, it was cheaper to buy almost everything outside of California. In this way, the gold originating in California found its way to the rest of the country and the rest of the world.

The same principle always applies, though when effective means of transportation exist, the disparity in prices need not be very great: the newly mined gold will be carried off rapidly and sufficient quantities of ordinary goods will be brought in rapidly, so that prices in the gold-mining areas will tend to exceed prices elsewhere by little more than the costs of transportation.

Alongside these two principles, and always limiting their operation, is a third principle, which is that, other things being equal, *the balance of trade and payments of all countries always tends toward balance*. That is, given the relative size of a country’s economy in the world economy, and given the total quantity of money in the

world’s economy, there is a tendency for the receipts and outlays of money of all countries respectively to equalize.

This principle exists by virtue of the effects of changes in the quantity of money in the different countries. Countries whose money supply increases through an excess of receipts over outlays experience a tendency toward rising prices, while countries whose money supply decreases through an excess of outlays over receipts experience a tendency toward falling prices. The resulting changes in prices makes the countries which have experienced an inflow of money relatively less favorable markets and those which have experienced an outflow of money relatively more favorable markets. Thus, the inflow and outflow of money is ultimately stopped. In other words, the balance of trade and payments comes into balance.

Whether the balance of trade and payments of a country were in balance or not in balance, there would always be a sufficient quantity of precious metals in every country to buy all that it is capable of producing and to employ all of its inhabitants who are able and willing to work. As later chapters will show, this is strictly a question of the prices and wage rates in that country. At the appropriate level of prices and wages, any given quantity of money and volume of spending is capable of purchasing the entire supply of goods that a country can produce and of employing its entire supply of labor.³⁹ Indeed, as the present discussion makes clear, the problem a country experiences of an outflow of precious-metal money accompanying a decline in its relative economic position in the world is the result of its *not having increased its production sufficiently*. What is required to stop such an outflow of precious metals is precisely an increase in its ability to produce.

In this connection, the potentially extremely destructive role of monopoly labor unions must be mentioned. Such unions play a major role in retarding the rise in the productivity of labor in a country and thus in bringing about a decline in its relative position in the world economy. This decline means, as a minimum, a slower rate of increase in the supply of precious metals in the country. This, in turn, means that full employment can be achieved only at a lower level of money wage rates than would otherwise be necessary—possibly at a level of money wage rates which represents an absolute fall. But the unions are unlikely to be willing to accept the relatively lower wage rates, and almost certainly not an absolute fall in wage rates. Thus, unemployment develops. And so long as the unions retard the rise in the domestic productivity of labor, while it goes on rising more rapidly abroad, the problem of unemployment worsens.

This point, of course, has application to current con-

ditions in the United States, even though the country is not on a gold standard of any kind. In a world of multiple fiat moneys, changes in the relative size of the economies of the various countries are still reflected in corresponding changes in the proportion of the world's money supply circulating within their borders. Only now, the change is effected partly by changes in the foreign exchange value of the various currencies and partly by changes in their respective quantities. The more rapidly production increases in one country relative to the others, the higher, other things being equal, becomes the value of its currency relative to the value of foreign currencies. By the same token, the more rapidly production increases in a country relative to other countries, the more rapidly can that country increase its quantity of money without depreciating the value of its currency relative to the value of foreign currencies. Thus, the fraction of the world's quantity of money that exists within the territory of a country is still determined by the size of its economy relative to the economy of the rest of the world.

It follows, even under the present system of multiple fiat moneys, that to the extent that labor unions in the United States have retarded the rise in the productivity of labor in the United States relative to that in foreign countries, they have caused a fall in the fraction of the world's money supply that circulates in the United States. It further follows that to the extent that they insist on continuing to receive wage rates conforming to a previous, higher relative productivity of labor in the United States, the effect must be unemployment.

These results exist in dramatic form in such major American industries as automaking and steel, where labor unions have greatly retarded the rise in the productivity of labor, at the same time that the productivity of labor in these industries in important foreign countries has sharply increased. The rise in the relative productivity of labor abroad has enabled foreign competitors to undersell American producers even while paying rapidly rising wage rates. The only thing that has prevented the unions from causing mass unemployment in the United States is the fact that many branches of industry in the United States are nonunion and have thus been in a position to absorb additional workers.⁴⁰

Inflation as the Cause of a Gold Outflow

I have already explained how the gold standard of the eighteenth and nineteenth centuries and the earlier part of this century was a fractional-reserve gold standard. Under such a gold standard, the world supply of money can be increased by the creation of fiduciary media in any given country. (This includes, of course, fiduciary media created by governments in issuing claims to gold in excess of their actual gold holdings.) So long as the

fiduciary media are accepted in commerce as the equivalent of gold, an increase in their supply appears on the market as though it were an increase in the supply of gold.

From this point on, the effects are largely analogous to those resulting from the discovery of additional gold mines in a country. The increase in the world's supply of money is initially concentrated in the country in which the additional fiduciary media are created. The effect is a disproportionate enlargement of that country's money supply relative to the money supply of other countries. On the foundation of this larger money supply, the inhabitants of the country step up their expenditures, including, of course, their expenditures to abroad. At the same time, prices in the country rise relative to prices in other countries. In addition, the appearance of the additional fiduciary media on the loan market operates to reduce interest rates in the country relative to interest rates abroad. For all of these reasons, an unfavorable balance of payments develops, as a substantial portion of the additional money supply begins to move abroad. Indeed, in the absence of the simultaneous creation of fiduciary media abroad, the only portion of the additional money supply which the country in question could retain would be the proportion corresponding to its proportion of the world's economy. That means, for example, that if it represented 5 percent of the world's economy, it could retain only 5 percent of the additional supply of money it created.

Here the analogy to the discovery of additional gold mines ends. For a country's additional fiduciary media are not in fact additional gold. And the additional money supply that foreigners will usually wish to hold is not the expanding country's additional fiduciary media, but a corresponding quantity of *gold*. Thus, the effect is that a loss of gold reserves ensues in the expanding country.

Of course, the loss of gold reserves resulting from the creation of fiduciary media is the less severe to the degree that the policy is pursued at the same time by other countries. To the extent that all countries expand fiduciary media at the same time, each will tend to have mutually offsetting claims against the gold reserves of the others. The policy can also be carried further to the extent that a country's fiduciary media are sought for holding in other countries, as was the case with the U.S. dollar in the decades following World War II, and, to a lesser extent, in the years following World War I.

Despite its actual cause, the gold outflow that occurs in such circumstances is typically blamed on the actions of the citizens, who, it is alleged, are spending too much for this or that category of import, travelling outside the country excessively, or lending abroad on too great a scale—as previously described.

Blaming the unfavorable balance of payments on the citizens and attempting to restrict their outlays to abroad (or stimulate their receipts from abroad) overlooks entirely the fact that the problem is the result of a *lack of demand for the additional money* in the country in which it originates. There is simply no basis for the citizens of the country wanting to retain the additional quantity of money all within its borders. And so long as this is the case, efforts to restrict their outlays to abroad for this or that specific purpose, such as French wines, tourism, or securities purchases, are absolutely futile. Their futility can be illustrated by imagining the case of someone who receives a \$500 check on his birthday and who wants to spend the money on a new suit, say. If this person is prohibited from buying the suit, the result will certainly not be that he then simply adds the \$500 to his cash holding. On the contrary, he will buy something else. If his second-choice expenditure, too, is prohibited, he will buy his third choice, and so on. If he is totally blocked from spending the additional \$500 for any purpose, he will reduce his other receipts of money by \$500, for there is no purpose in earning money he cannot spend. In no case can he be made to add the \$500 to his cash holding until he perceives a need to do so.

It is the same in international trade. If Americans are blocked from spending money for French wines, foreign vacations, or foreign securities, they will spend it for other things from abroad. This result is guaranteed, because so long as the additional money remains in the United States, it operates to make American prices higher than prices elsewhere, and does so to the degree that the additional money is retained in the United States, with the result that the more powerful is the encouragement of imports and, at the same time, the greater is the discouragement of exports. Thus, no sooner is one avenue of outlay to abroad blocked, than another is opened up, or receipts from abroad decline.

It should be realized that a corollary of the present discussion is that when the citizens of a country do have a demand for its existing quantity of money, no amount of outlays to abroad will for very long deprive them of any part of that quantity of money. Thus, for example, if, under an international gold standard, Americans want to hold their present quantity of money and American tourists happen to spend an additional billion or five or ten billion dollars touring Europe, that additional outlay will not reduce the quantity of money in the United States. Instead, it will automatically result in the generation of additional receipts from abroad, or in a reduction in other expenditures to abroad. It will do so in the same way and for the same reason that an individual who decides to buy some item that he likes does not finance the purchase of that item by reducing his normal cash holding.

For example, if someone normally needs to carry fifty dollars in his wallet and comes upon something he likes that costs forty dollars, which he decides to buy, that individual will not then decide to walk around with only ten dollars. He will quickly move to restore his cash holding, by withdrawing money from his savings account, say, or he will reduce his purchases of other items so that he can replenish his cash holding out of his next pay check. Indeed, to the extent that individuals know in advance that they will step up their expenditure for something, they first take steps to increase their receipts or to reduce their other expenditures. In any case, only in the most immediate and temporary sense are purchases made at the expense of running down cash holdings, unless the cash holdings were initially excessive.

To demonstrate, in as dramatic a way as possible, that outlays abroad are not made at the expense of running down cash holdings, when the cash holdings are not initially excessive, let us take the highly unpopular case of government outlays for foreign aid (which the present writer, of course, totally opposes). Let us imagine that a new foreign aid bill is passed and, as part of it, an army of tax collectors is dispatched into the streets to seize money from every passerby and from every shopkeeper and businessman. The money, we can imagine, is then loaded into armored cars, rushed to nearby airports, and then flown to various foreign capitals. Will this foreign aid be at the expense of the cash holdings of the American people? Will the American people now walk around and conduct their businesses with cash holdings diminished by the amounts the tax collectors have taken from them?

If one looks at matters subsequent to a span as short as a few days, the answer to these questions is no. The American people would immediately have to take steps to replenish their cash holdings. This is because at the prevailing level of wages and prices, their former cash holdings are necessary if they are to buy the things which they want to buy and to conduct their businesses on the scale on which they want to conduct them. Precisely their efforts to replenish their cash holdings would result in a rapid return of the funds that had been taken from them.

There would be substantial withdrawals of cash from banks, reductions in the expenditure for many items, and the widespread holding of sales by businessmen, as methods of raising cash. The effect of these actions would be a rise in interest rates and fall in the prices of various commodities in the United States. Meanwhile, in the foreign capitals, opposite results would be taking place. There, the presence of the additional cash would operate to reduce interest rates and raise commodity prices. The effect would be that the cash would probably be loaded back onto the very same planes on which it had arrived and be returned to the United States on practically

the very same day it had left.

The loss to the American people would take the form not of a reduction in their cash holdings, but of a diminution in the quantity of goods they were able to buy: the recipients of the foreign aid would have the funds to buy more goods, while Americans had to buy less goods. Also, the indebtedness of the American people would be increased, which they would have to repay by further restricting their consumption in favor of the recipients of the foreign aid. Of course, to some extent, instead of buying less, the American people would also have to sell more, in order to replenish their cash holdings. In other words, the foreign aid measure and the initial loss of currency it entailed would automatically be financed by a combination of a decrease in imports and increase in exports. It would not be financed by any significant loss of currency.

Considerations such as these fully confirm the observation of Adam Smith, quoted earlier in this section, that “the attention of government never was so unnecessarily employed, as when directed to watch over the preservation or increase of the quantity of money in any country.”

A final analogy will help to bring into focus what is wrong with the whole balance of payments approach.

Thus, if we had nothing better to do with our time, we might construct a “balance of food account.” This would show all sources of food entering a family’s refrigerator and all uses of the food taken from that refrigerator. The food entering the refrigerator, of course, would be the counterpart of receipts; the food taken from the refrigerator, of outlays. The change in the quantity of food in the refrigerator, of course, is always equal to the difference between the receipts of food entering the refrigerator and the withdrawals (outlays) of food leaving the refrigerator.

We might then appoint a government official to stand guard over the refrigerator and spend his time worrying about the food balance. We can imagine him watching the food in the refrigerator diminishing, and blaming it on excessive outlays for snacks or parties, or perhaps insufficient receipts from the nearby supermarket. We can imagine him rejoicing at the increase in the amount of food in the refrigerator when a bag of groceries is unpacked and put away. We can imagine him projecting plans and issuing regulations concerning what alleged excesses on the food-outlays side must be controlled and what alleged deficiencies on the food-receipts side must be overcome, in order to secure a stable or growing stock of food.

And, finally, we might imagine trying to explain to this good civil servant that the amount of food in the family’s refrigerator is not in fact the result of the hap-

penstance difference between receipts and outlays of food, but of deliberate decisions by the family to build up or run down its stock of food, which decisions determine the food receipts and outlays in such a way as to achieve the desired change in the stock of food. Thus, for example, if we observe the stock of food increasing, the explanation is not that food receipts exceed food outlays, but that the family has decided to give a party, say, and has gone out and done the necessary extra shopping. Similarly, if we observe the stock of food decreasing, the explanation is not that the amount of food being withdrawn from the refrigerator exceeds the amount being put into it, but that the family has decided to go away for a vacation and thus to use up the food it has without replacing it.

In sum, what needs to be explained is that the change in the stock of money in people’s pockets, like the change in the stock of food in their refrigerators, is fully within their control and that their decisions about changes in the stock determine the relationship between the receipts and outlays, not that the relationship between the receipts and outlays determines the change in the stock.

Unilateral Free Trade and the Balance of Trade

The analysis of the balance of trade/payments that has been given above sheds light on the effects of adopting a policy of unilateral free trade or unilateral tariff reduction.

Under an international gold standard, the adoption of such a policy would temporarily be accompanied by an “unfavorable” balance of trade/payments in the country concerned. This is because the immediate effect of the country’s elimination or reduction of trade barriers would be that foreign goods suddenly became cheaper, while domestically produced goods remained at their initial prices. Thus, the demand for imports would increase and there would be no immediate change in the quantity demanded of exports. Accordingly, under an international gold standard there would be an outflow of gold.

However, this very loss of gold and thus the reduction in the quantity of money in the country would operate to reduce wages and prices in the country, and to increase them in the countries to which the gold was sent. These changes, in turn, would make the country’s producers more competitive both in the domestic market of their country and in the international export market. The effect would be that some part of the domestic market initially lost to imports would be regained and at the same time an expansion of exports would take place.

Thus the country would end up both importing more and exporting more. Its citizens would be as fully employed as they were before. The only difference would be that more of them would be employed in export

industries and fewer of them in industries producing for the domestic market. The net gain of the citizens would be that the additional imports they obtained represented more and better goods than they could produce with the same labor devoted to producing for the domestic market. By the same token, the citizens of foreign countries would gain more from the additional exports of the country in question than they lost by devoting part of their labor to producing the additional imports for that country. In other words, both the citizens of the country in question and the citizens of the countries it dealt with would enjoy greater benefits from the operation of the law of comparative advantage.⁴¹

An essential requirement of being able to adapt to the consequences of a temporary outflow of money is the absence of labor legislation. This is because it is vital that the wage and price level of the country be free to fall to the extent necessary for the country to become sufficiently competitive to have full employment. Precisely this is what such legislation prevents.

The present discussion provides the opportunity to deal with the question of what would happen if one country pursued a policy of free trade, while all other countries absolutely prohibited the importation of its goods.

In such a case, under an international gold standard, the country would experience an outflow of gold until its wages and prices fell so low, and those in other countries rose so high, that its citizens simply wished to purchase nothing whatever from abroad.

The existence of such a case is virtually impossible, however. As wages and prices in the country concerned fall, its goods become an ever more powerful attraction to foreign buyers. Thus, it is almost unthinkable that it would not at some point increase its exports. To whatever extent it is able to do so, then its citizens—and the citizens of foreign countries—gain the benefit of greater operation of the law of comparative advantage.

It should be obvious that if unilateral free trade is viable under the conditions of an international gold standard, and, indeed, even under conditions in which, in addition, other countries follow policies of the most extreme protectionism, then it should certainly pose no great difficulties under the conditions of a fiat money, in which there cannot even be any significant outflow of money.

5. Invariable Money

Under the head of money, it is essential to deal with the concept of *invariable money*, whose meaning and vital role in economic analysis I will at once proceed to explain.

When prices change, people usually take for granted that the change is the result of something taking place on the side of goods. When prices rise, they say that goods are becoming more expensive; when prices fall, they say that goods are becoming cheaper.

This presumption was overthrown when economists realized that money itself is subject to the same forces of supply and demand as are goods. This realization meant that changes in prices can reflect changes taking place on the side of money as well as changes taking place on the side of goods. Indeed, precisely this is the case whenever there is inflation or deflation. During an inflation, it is not actually goods which are becoming more expensive, but *money* which is becoming cheaper. During a deflation, it is not actually goods which are becoming cheaper, but money which is becoming dearer. The rise in prices during an inflation is the result of expressing them in a medium that is itself of declining value; the fall in prices during a deflation is the result of expressing them in a medium that is itself of rising value. This point has already been made clear in the example of expressing the lower price of video tape recorders in terms of pocket calculators, whose price has fallen even more, which produces the result of the price of video tape recorders appearing to rise rather than fall.⁴²

That example, and its underlying theoretical insight, should not be thought of as esoteric in any way. They help to shed a great deal of light on, among other things, the respective roles of a system of fiat paper money and the businessman's profit motive in the causation of the rising prices we see almost all around us. It is a fact that prices are rising. But it is no less a fact that the profit motive of the businessman tends constantly to reduce prices. The two facts are reconciled by the third fact that we currently express prices in terms of a monetary unit whose own value falls more rapidly than businessmen are able to cut costs and reduce prices. Our present monetary unit is, of course, a mere piece of paper, whose cost of production is virtually zero to begin with, whose quantity can be expanded without limit, and which is in fact rapidly expanded. Thus, prices rise even though, if expressed in a monetary unit whose own value did not decline, they would show a pronounced fall.⁴³

The variability of the value of money coming from the side of money does not apply only to a fiat paper money, however. It applies even to a pure gold or silver standard—that is, to a 100-percent-reserve gold or silver standard. The supply of gold and silver tends to increase, which, other things being equal, operates to reduce their value, i.e., to raise the prices of all other goods. Of course, the increase in the supply of precious metals tends to take place in conjunction with an increase in the supply of goods and services in general and thus tends not to result

in an actual rise in prices. Moreover, because the increase in the supply of precious metals is relatively slow and steady and the supply virtually incapable of any significant sudden decrease, the demand for the precious metals would tend to be highly stable under a 100-percent-reserve, precious-metal standard. But even so, the increase in the supply of precious metals would still operate to make the fall in commodity prices less than it would otherwise be, i.e., to raise commodity prices in comparison with what they would have been in the absence of any change in the supply of the precious metals.

When economists realized that even a gold money is regularly subject to forces that tend to change its value from the side of money, they launched a search for a money of *invariable value*—that is, for a money under which changes in prices would reflect exclusively changes operating on the side of goods, not money. These efforts, and the recognition of their importance, were carried furthest by Ricardo, who declared:

If then, I may suppose myself to be possessed of a standard so nearly approaching to an invariable one, the advantage is that I shall be enabled to speak of the variations of other things without embarrassing myself on every occasion with the consideration of the possible alteration in the value of the medium in which price and value are estimated.

To facilitate, then, the object of this inquiry, although I fully allow that money made of gold is subject to most of the variations of other things, I shall suppose it to be invariable, and therefore all alterations in price to be occasioned by some alteration in the value of the commodity of which I may be speaking.⁴⁴

Ricardo believed that in order for gold to be an invariable standard of value, the principle requirement that it would have to fulfill is always to require the same quantity of labor in its production. Even then, he held, it would not be perfect as an invariable standard of value, because changes in the rate of profit and in the period of time elapsing between the performance of labor in the production of gold and the exchange of that gold in the market could alter its value from its own side.⁴⁵

In my judgment, Ricardo's discussions of an invariable standard of value and his applications of the concept, while essentially brilliant, are badly flawed and needlessly obscured by his constant intermingling of the labor theory of value. Thus, in place of Ricardo's criteria for an invariable monetary standard, I offer my own, whose nature has been indicated in previous pages of this book. Namely, what would be required for gold to be an invariable standard of value would be a *fixed, constant aggregate expenditure of gold for products*—e.g., a fixed aggregate expenditure for products of one billion ounces of gold per year.⁴⁶ This would be consistent with a fixed quantity of gold money and a fixed velocity of circulation

of that money in relation to products. The latter requirement, of course, would be consistent with an essentially fixed demand for gold for holding.

Under these conditions, price changes on the aggregate level—that is, changes in the weighted average or general level of prices—would reflect changes taking place on the side of the production and supply of products exclusively. Indeed, the implication of a fixed aggregate expenditure is that the aggregate demand curve for products would be such that all changes in the aggregate supply of products produced and sold would result in *inversely proportionate* changes in the weighted average of product prices. That is, if production and supply doubled, prices would halve. If they tripled, prices would be cut to one-third, and so on. This follows because an unchanged aggregate expenditure means that it is represented by the number “one.” Whatever the increase in production and supply, it is always divided into one. Hence, the price level is always the reciprocal of production and supply. In the technical language of economists, the aggregate demand curve would have unit elasticity, which is to say that quantities of products demanded would change in inverse proportion to prices.

Changes in demand, of course, would, still take place in the economic system, but only at the level of individual industries and companies. At the aggregate level, they would always be mutually offsetting. If expenditure for product *X* increased, then expenditure for product *Y*, or for a group of products denoted as *Y*, would have to decrease equivalently. Thus changes in demand would be a factor determining relative prices only, not the general level of prices. All changes in the prices of individual goods would reflect changes specific to those goods, including the evaluation of those goods, not changes operating on the side of money.⁴⁷

Invariable Money and the Velocity of Circulation

The concept of an invariable money should not be confused with the assumption of an invariable velocity of circulation of money other than that of an invariable velocity of circulation confined to the demand for products only. It is consistent with substantial variations in overall total expenditures relative to the same total quantity of money and thus with substantial variations in broader measures of velocity, such as transactions velocity and “total revenue velocity,” which last would relate the combined sum of expenditures either for products or for labor to the quantity of money.⁴⁸ This is because changes in the demand for securities and in lending and borrowing operations need have no effect on changes in the aggregate demand for products inasmuch as the sellers of securities and the recipients of loans can simply take the place of the buyers of securities and the grantors

of loans in making purchases of products.⁴⁹ In the same way, a rise in the demand for labor that is made possible by a fall in the consumption expenditure of employers enables wage earners to make a demand for products in place of their employers and thus also does not reduce the demand for products. The same is true even of taxation insofar as it transfers the ability to buy products from the taxpayers to the government or to other individuals to whom the government gives the tax proceeds.

Thus the aggregate demand for products can remain the same on the foundation of a fixed quantity of money in the economic system, while other forms of expenditure increase or decrease.

The Contribution of the Concept of Invariable Money to Economic Theory

The concept of an invariable money is an invaluable tool of economic analysis. (It should go without saying that as an analytical tool, it should not be confused with any kind of objective to be established by government intervention in the economic system. It is a method to be used in thinking about the economic system, not a political goal to be imposed upon it.) A few paragraphs ago, I recalled its value in reconciling the benevolent nature of the profit motive with the existence of rising prices. It should also be recalled how an analysis based on the assumption of an invariable money served to reconcile the benevolent nature of economic competition with reductions in money income on the part of less capable competitors. For it showed how competition operates to reduce prices to the same extent as it operates to reduce the incomes of the less capable competitors and, indeed, to a greater extent.⁵⁰

Applying the concept of an invariable money permits the separate analysis of the effects of changes operating on the side of the production and supply of goods and services, and changes operating on the side of money and the monetary demand for goods and services. Its application thus makes possible the adoption of a procedure analogous to that of mechanics, which takes as its analytical starting point the existence of a vacuum and then proceeds to develop its basic laws in a context in which there is no friction and in which, therefore, it can conceptually isolate the effects of the forces operating on objects. Indeed, the assumption of an invariable money is and must be made at least implicitly by everyone who thinks about economic phenomena insofar as his theorizing is based on the assumption of all other things being equal, which, of course, is the necessary starting point of all economic analysis. Among the most important of the other things that must be held equal in economic analysis is the quantity of money and the aggregate spending for the goods and services of business that it supports. In-

stead of leaving the assumption to mere implication, however, it should be made explicitly and adhered to unless and until it is necessary to relax it.

Accordingly, my typical procedure in the chapters that follow will be to begin with the assumption that the quantity of money and aggregate volume of spending in the economic system for the goods and services of business are fixed. With the aid of this analytical context, we will be in a position to trace out in isolation the effects of all phenomena acting on the production and supply of goods—for example, such phenomena as an increase in the productivity of labor resulting from the adoption of improved machinery or any other cause, or an increase in the supply of labor, whether an increase in the number of workers employed or an increase in the number of hours or days worked by the average employed worker. We will be able to examine the effects of all such changes on prices, wage rates, average money incomes, and the average standard of living. Then, in a separate analytical procedure, we will trace out the effects of an increase in the quantity of money and volume of spending in the economic system. Finally, in a manner similar to the addition of separate vectors in mechanics, we will add the results of the two separate analytical procedures in order to arrive at a complete description of what occurs in the world around us.

I will name now some of the leading findings that this method will reach. It will validate the proposition known as Say's Law of Markets, that aggregate real demand—that is, what any given aggregate monetary demand can actually buy—is determined by aggregate supply. It will confirm the corollary proposition of the classical economists that a general or absolute overproduction is impossible—that the only kind of overproduction that can exist is a partial, relative overproduction in some portions of the economic system, which is always counterbalanced by a precisely equivalent partial, relative underproduction elsewhere in the economic system. In close connection with these points, our method will show that the falling prices caused by increased production do not constitute deflation, in that they are not accompanied by the other leading symptoms of deflation, namely, a greater difficulty of repaying debts and a decline in the general profitability of business. It will show that deflation properly so called is always a phenomenon operating on the side of money, in the form of a reduced supply and/or increased demand for money and thus in a reduction in aggregate expenditure.

Economic analysis based on the context of an invariable money will show not only that unemployment can be eliminated by means of a fall in wage rates and prices but, at the same time, that the restoration of full employment achieved in this way tends to be accompanied by a

rise in the *real* wages of the average worker—that is, by a rise in the goods and services he is actually able to buy with his money wages. Here, such analysis shows, is a major case in which money wages fall and nevertheless real wages rise—in which, indeed, the fall in money wages is the precondition of the rise in real wages. Economic analysis based on the context of an invariable money will show that real wages are determined primarily and overwhelmingly by the productivity of labor, while the average level of money wages is determined primarily by the quantity of money.

This method of economic analysis will lead to the further conclusion that the rate of increase in the quantity of money and volume of spending in the economic system adds a roughly equivalent increase to the average nominal rate of profit and interest, while the rate of increase in the volume of production and supply of goods adds a roughly equivalent increase to the average real rate of profit—that, for example, a 2 percent annual increase in the quantity of money and volume of spending in the economic system add approximately 2 percent to the nominal rate of profit, while a 2 percent annual increase in the volume of production and supply add approximately 2 percent to the real rate of profit. Analysis on the basis of an invariable money will also make it possible to grasp the determinants of the nominal rate of profit *other* than the rate of increase in the quantity of money.

In addition, economic analysis based on the context of an invariable money will make it possible for the first time to grasp the actual relationships between saving, on the one side, and capital accumulation, real wages, and the rate of profit, on the other, and to discern causes of capital accumulation which otherwise must remain concealed—notably, technological progress and anything else which operates to increase production. It will show, among other things, that the value of technological progress in connection with capital accumulation is as a *source* of capital accumulation, not as a use of capital goods accumulated by saving. It will show that nominal net saving, i.e., saving out of money income, is possible as a permanent phenomenon only on the basis of an increasing quantity of money and would disappear if the increase in the quantity of money were to come to an end. It will show that the real significance of saving is to be found at a level beyond that of money income, namely, in the proportion of gross revenue saved and productively expended versus the proportion consumed, and in the ratio of accumulated nominal capital to consumption. It will show that capital accumulation does not in any way necessitate or imply a falling rate of profit, and that even nominal net saving also does not imply a falling rate of profit in the context in which it continues indefinitely,

namely, that of an expanding quantity of money.

A major theme which develops on the basis of the analytical framework of an invariable money is that of the distinction between monetary value and real wealth, or, as Ricardo put it, the distinction between “value and riches.”⁵¹ It will become apparent how mistaken it is to assume that wealth and the monetary value of wealth necessarily move together. For again and again, it will become clear how production and real wealth can increase at the same time that alleged monetary measures of that production and wealth, such as national income or gross domestic product (gross national product), show no increase or actually decrease, and, by the same token, how alleged monetary measures of production and wealth can increase while the production and wealth involved actually tend to decrease.

Thus, we have already seen how competition among workers can reduce the money incomes of broad categories of workers and yet still be the basis of a rise in the general standard of living, including the standard of living of the workers whose money incomes are reduced. Going even further, we will see how capital accumulation and improvements in machinery are capable of being accompanied by reductions in the money income of all wage earners taken together, and yet at the same time still be the basis of a rise in the standard of living of the average wage earner.⁵² Indeed, we will see that the whole mentality, which is so typical of the labor unions, that the way to raise the standard of living is to raise money wages is completely mistaken when applied to the economic system as a whole. It will become clear that the rise in the general standard of living always takes place from the side of forces tending merely to reduce prices, and not to increase money incomes, indeed, tending sometimes to reduce money incomes. We will see also that forces operating to increase average money incomes can, at the same time, be the source of a fall in real incomes, and that this is true not only of the undue increase in the quantity of money, viz., inflation, but also of taxes paid for with funds that otherwise would have been expended to buy capital goods, and of government budget deficits similarly paid for. Such taxes and deficits, we will see, operate to raise pretax nominal profits and, at the same time, to undermine capital formation and reduce the ability to produce and thus the general standard of living.⁵³

Perhaps among the greatest instances of the distinction between value and riches is the one we have seen in the preceding chapter. I refer, of course, to the fact that in Adam Smith’s “early and rude state of society,” all income would be profit and the rate of profit would be infinite, while at the same time the level of production and general standard of living would be barbarously low.

Under the assumption of an invariable money, advance from such a state of affairs would be accompanied not only by a fall in the nominal rate of profit, but also by a fall in the size of nominal national income (national income being taken as the sum of profits plus wages). For as productive expenditure grew, not only would wages rise at the expense of a fall in profits, but so too would the expenditure for capital goods and thus costs on account of the expenditure for capital goods. In other words, the fall in profits would exceed the rise in wages, as what had been profits became both wages and a demand for capital goods. Yet real wealth and prosperity would be the greater and all the more rapidly progressing, the further this process was carried.

While the distinction between value and riches—between the effect of things on money income and their effect on the actual standard of living—is at its sharpest in the context of an invariable money, it also appears again and again in the world around us. The explicit assumption of an invariable money is essential to understanding the nature of economic phenomena by thinking through the full consequences of their operation and not stopping at the point merely of recognizing their positive or negative effect on money income. When this is done, the benevolent nature of the pursuit of material self-interest under economic freedom, and the destructive nature of government violations of economic freedom, stand forth in unparalleled clarity and completeness.

Notes

1. The time of writing is the fall of 1994. The figure for the money supply comes from *The New York Times*, October 28, 1994, p. C13, while the estimate for the GDP is based on the data reported for the second quarter of 1994 in *The Federal Reserve Bulletin*, October 1994, p. A51.

2. See *ibid.*, p. A14. This measure of the money supply is reported as M_1 . Other, larger measures add to M_1 such totals as time and savings deposits, certificates of deposit, Treasury Bills, and so forth. These further items are easily convertible into money and represent highly liquid assets. But they are not directly spendable as such. One cannot, for example, walk into a store and spend directly out of one's savings-account passbook, as one can spend out of one's checkbook. Such assets can be thought of as near moneys, but they are not in fact money themselves. Concerning a recent important development pertaining to this subject, see below, p. 965 n. 100.

3. See *ibid.*, p. A51. Both government expenditures—virtually in their totality—and private expenditures for owner-occupied housing must be categorized as consumption because, as previously explained, they are not made for the purpose of bringing in subsequent sales revenues. Hence, they lack the ability to replace the funds expended in carrying on the activity. Those funds are used up and gone—consumed. If they are to be replaced, it must be from an outside source of revenue: taxes or money creation in the case of the government, a job or business in the case of private individuals. See above, pp. 442–456.

4. The reasons for this equivalency with national income are explained below, on pp. 700–702 and on p. 712.

5. The concept of Gross National Revenue is elaborated below, on p. 712.

6. See below, pp. 519–526, for a whole series of further connections between more money and more demand.

7. These definitions, of course, accord with the usage of the British classical economists, which was explained in Chapter 5. The demand/supply formula was also present implicitly in Chapter 6, in my exposition of the theory of price formation for goods and services in limited supply, and more or less explicitly in Chapter 7, in my discussion of price controls and inflation.

See above, pp. 152, 202, and 220.

8. See above, p. 220.

9. See above, pp. 141–142.

10. In most of its essential features, this discussion of the origins and evolution of money follows the writings of Menger. Cf. Carl Menger, *Principles of Economics*, trans. and ed. by James Dingwall and Bert F. Hoselitz (Glencoe, Ill.: The Free Press, 1950), pp. 257–271, 280–285.

11. See above, p. 142.

12. Menger did not emphasize this advantage of the precious metals. As a result, his account of why the precious metals in particular became money is highly deficient. See Menger, *Principles*, pp. 265–268.

13. Gold and silver rarely circulated at the same time, because of government interference in the form of bimetallism, that is, the imposition of a price control on one or the other of the two moneys. Prior to 1834, the government compelled merchants to accept gold coin as the equivalent of only 15 ounces of silver to one ounce of gold, while in the bullion market gold was worth about 15.5 ounces of silver. The result was that gold did not circulate in this period. From 1834 on, the government required that silver coin be accepted at the rate one ounce of silver equals one-sixteenth of an ounce of gold, while in the bullion markets it was more valuable. The result was that silver coins disappeared from circulation.

15. *Federal Reserve Bulletin*, October 1994), p. A13.

16. Charles Holt Carroll, a nineteenth-century monetary theorist, aptly described the phenomenon as “the organization of debt into currency.” See his *Organization of Debt Into Currency, and Other Papers*, ed. with an Introduction by Edward C. Simmons (1964; reprint, New York: Arno Press and The New York Times, 1972).

17. Until the mid-1970s, only commercial banks could offer checking accounts. Now more than half of total checking

accounts are held at other types of financial institutions, such as savings banks and savings and loan associations.

18. See Murray Rothbard, *What Has Government Done to Our Money?* (Novato, Calif.: Libertarian Publishers, 1979), pp. 22–24. In support of this view, see also below, pp. 957–958.

19. Cf. von Mises, *Human Action*, p. 446.

20. The best explanations of the trade cycle are to be found in von Mises, *Human Action*, pp. 398–586, 780–803, and Charles Holt Carroll, *The Organization of Debt Into Currency*.

21. *Federal Reserve Bulletin*, October 1994, p. A10.

22. On this subject, see *New York Times*, March 26, 1992, pp. C1–C2.

23. For the sake of brevity, in what follows I generally refer to gold and gold money, but, of course, my discussion applies equally to silver and silver money.

24. The destructive effects of fiduciary media become apparent in the light of this principle. See the discussion of the effects of credit expansion on the demand for money, below, p. 256. See also below, pp. 938–940.

25. Compared with rates of increase in the supply of paper money, even the gold added by the Spanish conquest of the new world and later by the California gold fields was relatively modest. See below, p. 920.

26. See below, pp. 942–950.

27. Cf. von Mises, *Theory of Money and Credit*, pp. 227–229; *Human Action*, pp. 426–428.

28. For reasons that I will explain in the next chapter, in connection with the discussion of Say's Law, falling prices caused by increases in production, rather than by decreases in the quantity of money and volume of spending, do not operate to increase the demand for money or, therefore, to reduce the velocity of circulation of money. Only those price reductions emanating from decreases in the quantity of money and/or volume of spending cause a rise in the demand for money. See below, pp. 574–576.

29. Chapter 19 explains why credit expansion is followed by periods of credit contraction and thus of deflation and depression. See below, pp. 938–941. See also von Mises, *Human Action*, pp. 538–586.

30. See above, pp. 186–187.

31. See below, pp. 762–774.

32. This calculation is based on data supplied in *Banking and Monetary Statistics 1914–1941*, p. 34.

33. Cf. *Federal Reserve Bulletin*, December 1982, p. A14; December 1983, p. A13. See below, p. 965 n. 100, concerning the more recent role of money-market mutual funds.

34. The calculation of the most recent rate of increase in the money supply is based on year-end data appearing in *Federal Reserve Bulletin*, July 1994, p. A14, and weekly money supply figures as reported in *New York Times*, October 17, 1994.

35. See below, pp. 959–962.

36. See below, pp. 942–950, especially pp. 946–949.

37. Adam Smith, *The Wealth of Nations* (London, 1776), bk. 4, chap. 1; reprint of Cannan ed., (Chicago: University of Chicago

Press, 2 vols. in 1, 1976), 1:458.

38. For the most part, the foreigners' bank deposits are saving or time deposits, or take the form of the purchase of certificates of deposit.

39. See, for example, below, pp. 542–594 passim.

40. For further discussion of the destructive effects of labor unions, see below, pp. 655–659.

41. For a discussion of the law of comparative advantage and its relationship to international competition and to competition in general under capitalism, see above, pp. 350–356.

42. See above, pp. 179–180.

43. Cf. above, *ibid.*

44. David Ricardo, *Principles of Political Economy and Taxation*, 3d ed. (London, 1821), chap. 1; reprinted as vol. 1 of *The Works and Correspondence of David Ricardo*, ed. Piero Sraffa (Cambridge: Cambridge University Press, 1962), p. 46. Subsequent page references to the Sraffa edition will appear in brackets.

45. *Ibid.* [pp. 43–46].

46. In most contexts, but not all, the fixed aggregate demand for products can be taken as pertaining simply to newly produced products. For a leading exception, however, see below, pp. 578–579. Those pages contain an analysis in which the demand for products must be extended to include the demand for previously produced products.

47. The assumption of an invariable money in my sense, that is, of a fixed aggregate expenditure for products, appears implicitly throughout much of Henry Hazlitt's *Economics in One Lesson* and Bastiat's "What Is Seen and What Is Not Seen," and is a major source of the great analytical strength of those works. See Henry Hazlitt, *Economics in One Lesson*, new ed. (New Rochelle, N. Y.: Arlington House, 1979) and Frederic Bastiat, *Selected Essays on Political Economy*, trans. Seymour Cain (New York: D. Van Nostrand, 1964), pp. 1–50.

48. For discussion relevant to the concept of total revenue velocity, see below, pp. 706–707.

49. Indeed, if anything, such transactions are part of a process that actually serves to increase the demand for products. See above, the discussion of the effect of saving on the velocity of money, on p. 518.

50. See above, pp. 367–371.

51. Cf. Ricardo, *Principles of Political Economy and Taxation*, especially chap. 20.

52. Ironically, Ricardo himself was led astray from his principle when he came to cases entailing a change in the aggregate demand for labor. Thus, he came to the mistaken conclusion that the adoption of machinery is against the interests of wage earners if it reduces the aggregate demand for labor and that war is in the interests of wage earners insofar as taxation diverts funds from expenditure for luxury goods to an additional demand for labor. Cf. *ibid.*, chap. 31. See the analysis of Ricardo's errors on these points, below, on pp. 639–641 and 647–650.

53. See below, pp. 826–830. This point applies to the so-called balanced budget multiplier doctrine of the Keynesians, concerning which, see below, pp. 712–715.

CHAPTER 13

PRODUCTIONISM, SAY'S LAW, AND UNEMPLOYMENT

PART A

PRODUCTIONISM

The identification that the fundamental problem of economic life is how steadily to increase the ability to produce in the face of a limitless need and desire for wealth, is one of the great achievements of the British classical economists.¹ This identification, together with its implications for the understanding of the effects of such phenomena as the use of machinery, advertising, a rise in the birthrate, foreign trade, imperialism, war, and government spending, I term *productionism*.²

Productionism is intimately bound up with a series of further propositions which the classical economists advanced, or which are clearly implied in their teachings. We have already examined a number of these propositions, among them: the central importance of the division of labor in raising the productivity of labor; the law of comparative advantage, which, together with the limitless need for wealth, guarantees a place for everyone in the division of labor, provided only that the freedom of competition exists; and the quantity theory of money. We have seen the clear implication of the quantity theory of money that depressions are caused by government sponsorship of a fractional-reserve banking system, which increases the quantity of money unduly, thereby artificially reducing the demand for money and raising its velocity of circulation, thus setting the stage for a subsequent financial contraction, deflation of the money supply, and depression. In Part B of this

chapter, we shall see how production and supply, and only production and supply, create purchasing power and thus demand in its real sense—i.e., in the sense of the goods and services a monetary demand can actually buy. This is the classical economists' proposition that has come to be known as Say's Law of Markets.³ In close connection with Say's Law, we shall come to understand the corollary proposition that the existence of a general overproduction—i.e., of an excess of aggregate supply over aggregate demand—is an impossibility. In Part C of this chapter, we shall also see how mass unemployment is the result of government intervention, not the workings of a capitalist economy itself.

While the present chapter shows how the productive process generates an aggregate real demand that is equal to aggregate supply and grows precisely as aggregate supply grows, subsequent chapters will show how the productive process also generates an aggregate monetary demand that in the absence of government interference is sufficient to buy the aggregate supply at a profit—that is, how the productive process itself inherently operates to make production financially profitable to the businessman of average skill and ability. Along the way, we shall see how, as the classical economists put it, “what is saved is spent,” indeed, is the source of most spending in the economic system, and more, underlies both a growing aggregate real demand for goods and services and a growing aggregate monetary demand for them. All of these doctrines of classical economics are closely related to productionism in the sense both of supporting it and being supported by it.

The one proposition connected with productionism which will be advanced and which may appear as a significant departure from the central ideas of the classical economists, but which actually is entirely consistent with them at the most fundamental level, is that real wages and thus the average worker's standard of living are determined by the productivity of labor. This proposition, indeed, is actually nothing more than the idea behind Say's Law applied to wages: real wages are determined by production, just as the real demand for goods is determined by production. Thus throughout, productionism and its related propositions are integrally connected to classical economics.

Productionism Versus the Anti-Economics of Consumptionism

In the twentieth century, there has been a growing influence of irrationalist philosophy, which denies the reliability and efficacy of human reason and which disregards the profound influence that the possession of reason exerts on every aspect of human life. According to such philosophy, there is little to distinguish man from the lower animals. Indeed, as we have seen, man is depicted as "the trousered ape"; porpoises, it is asserted, may possess intelligence comparable to man's; snail darters, we are told, have equal rights with man.⁴ Thus, at bottom, man, it is held, is just another animal. On such a view of man, it follows that man's needs and desires must be as limited as those of an animal and thus fundamentally incapable of extending beyond the range of minimum necessities. The fact that man's desires obviously do extend beyond the range of an animal's is held to be the result of "social and cultural conditioning" and the work of advertisers; at the same time, the desires are denounced as "unnatural," "artificial," and "created." Thus, the basic economic premise is advanced that the need and desire to consume are essentially fixed and given, and that the ability to produce threatens constantly to outrun them.

This premise, together with its leading implications, I call *consumptionism*. It is the doctrine that the fundamental problem of economic life is how to increase the need and desire to consume in the face of an ability to produce that exceeds them. Consumptionism proceeds as though the problem of economic life were not the production of wealth, but the production of *consumption*.

The consumptionist premise must be characterized as nothing less than the premise of *anti-economics*. This is because, as we shall see, point by point, it leads to a total inversion of the conclusions of sound, rational economic science.

While directly implied by irrationalist philosophy, the

consumptionist premise also results from the error of considering the effects of things only on those most directly concerned, and neglecting the effects on the rest of the economic system.⁵ Very importantly, among the leading practitioners of this error are businessmen who are in the habit of being concerned exclusively with the effects of things on their own industry.

In the context of an individual industry, the emergence of a need or desire for the product of the industry that is strong enough to outrank the need or desire for the products of other industries will channel spending to this industry from other industries. For example, if people developed a greater desire for automobiles, say, to the point that they were willing to cut back on their expenditures for housing or clothing, say, the demand for automobiles would increase. Conversely, if they developed a greater desire for housing or clothing, to the point that they were willing to cut back on their expenditure for automobiles, the demand for housing or clothing would increase. To unthinking businessmen in the industry experiencing the increase in demand—businessmen who do not stop to consider the accompanying offsetting decrease in the demand for the products of other industries—it appears simply that an increase in the need or desire for their product has increased the demand for their product. Because they are unaware of the offsetting effects on the demand for the products of other industries, such businessmen then come to the conclusion that what is required to increase the aggregate, economy-wide demand for products is an increase in the overall, economy-wide need for products, and that what is responsible for the slack demand for products in a depression is a lack of need for products. Thus, such businessmen are led to the same conclusion that is arrived at on the foundation of irrationalist philosophy, namely, that the ability to produce exceeds the need and desire to consume and that the problem of economic life is not the production of wealth but of the consumption of wealth.

Of course, what is overlooked by all such observers, whether businessmen or others, is that every increase in the demand for the product of a particular industry that is based on the need or desire for its product intensifying and thus pushing ahead of the needs and desires for the products of other industries and coming to the forefront, must be accompanied by an equivalent decrease in the demand for the products of other industries.

When this is borne in mind, it becomes clear that the need and desire for goods count in demand only insofar as they operate to determine *to which of various possible competing alternatives demand is directed*. Yet to those myopically concerned only with a particular industry, it mistakenly appears that because any given industry, at one time or another, could experience an increase in

demand by virtue of the need or desire for its product gaining in priority relative to the need and desire for the products of other industries, that *all industries might gain in this way at the same time*. This is a case of adding up as additional demands what are in fact a series of mutually exclusive alternatives, each of whose individual existence is predicated on an equivalent decline in demand in the rest of the economic system. This is a glaring example of what logicians call “the fallacy of composition,” that is, invalidly generalizing from what occurs in part of a system to the system as a whole.

When the actual nature of the relationship of the need and desire for goods to demand is kept in mind, it also becomes clear that any increase in the overall volume of mere need and desire—unaccompanied by an increase in the production and supply of goods—is irrelevant to the economy-wide, aggregate demand for goods. The mere need and desire for goods are always vastly in excess of demand in the economy as a whole, as was shown at length in Chapter 2. For example, I have a desire for luxurious houses or apartments in Paris, Rome, and Palm Beach, but I can barely make a *demand* for the one relatively modest home that I do occupy. If demand in fact depended merely on the need and desire for goods, and greater demand followed from the existence of a greater need and desire for goods, then the proportion of the world’s demand for goods that emanates from India and China would far exceed the proportion that emanates from the United States and Japan. Nevertheless, despite the fact that the populations of India and China far exceed those of the United States and Japan, and the unmet needs and desires of the average Indian and Chinese exceed those of the average American or Japanese by the magnitude of the formers’ lower standard of living, the demand for goods in the United States and Japan enormously exceeds the demand for goods in India and China. The explanation of this difference in demand is the difference in the ability to produce and supply goods, which, as we shall see in Part B of this chapter, is the cause of corresponding differences in *purchasing power*, which must be joined to need and desire in order to create demand. The United States and Japan are greater demanders of goods because they are greater producers, therefore, possess greater purchasing power, and can satisfy their needs and desires to a correspondingly greater extent.⁶

Thus consumptionism flourishes both because of the growing prevalence of an irrationalist view of man and his needs and desires and because of the widely practiced fallacy of looking at the effects of things only on those who are most directly concerned.

In this environment, economists, largely under the influence of Lord Keynes, and, still more, the hordes of

intellectuals who have no familiarity with economics, have returned to the view of economic life that was advanced by the predecessors of the classical economists, the mercantilists. Instead of taking the need and desire to consume for granted and focusing on the ways and means by which production might be increased, the problem of economic life is now often believed to be how to expand the need and desire to consume so that consumption may be made adequate to production. Much of what passes for economic thinking in the twentieth century takes production for granted and focuses on the ways and means by which consumption can be increased. It proceeds, as I have said, as though the problem of economic life were not the production of wealth, but the production of consumption. It was in this spirit that Keynes declared: “Pyramid-building, earthquakes, even wars may serve to increase wealth”⁷

Because of the prevailing influence of consumptionism and the major economic errors inspired by it, my procedure here will be to present those errors, one after another, accompanied by the answers of sound economics, based on the philosophy of productionism.

1. Depressions and Alleged “Overproduction”

According to the “overproduction” doctrine, it is possible for the aggregate supply of goods produced in the economic system to exceed the aggregate demand for them, that is, to exceed the need and desire for goods—which is the sense in which the concept “demand” is understood by the doctrine’s supporters. The demand for goods, it is claimed, may simply not be adequate to the rising level of production made possible by economic progress. According to the overproduction doctrine, the need or the desire for the growing volume of goods is simply lacking. People allegedly need and desire only so much, and not an ever increasing amount. Thus when production increases, producers are allegedly put in the position of producing more than the buyers are willing to buy, with the consequence that a depression results.

(Sometimes the supporters of the overproduction doctrine offer a variant of the doctrine. They claim that while the need and desire to buy the growing volume of goods may be present, the *ability* to buy them is lacking because people do not possess a correspondingly larger quantity of money. Here, instead of confusing demand with need, they confuse the ability to buy goods with the ability to spend money. As we shall see, the ability to buy goods—purchasing power—does not depend on the quantity of money and the ability to spend money, but on the volume of production and supply.⁸)

The overproduction doctrine can be understood graphically, in terms of Figure 13–1, which is titled “The

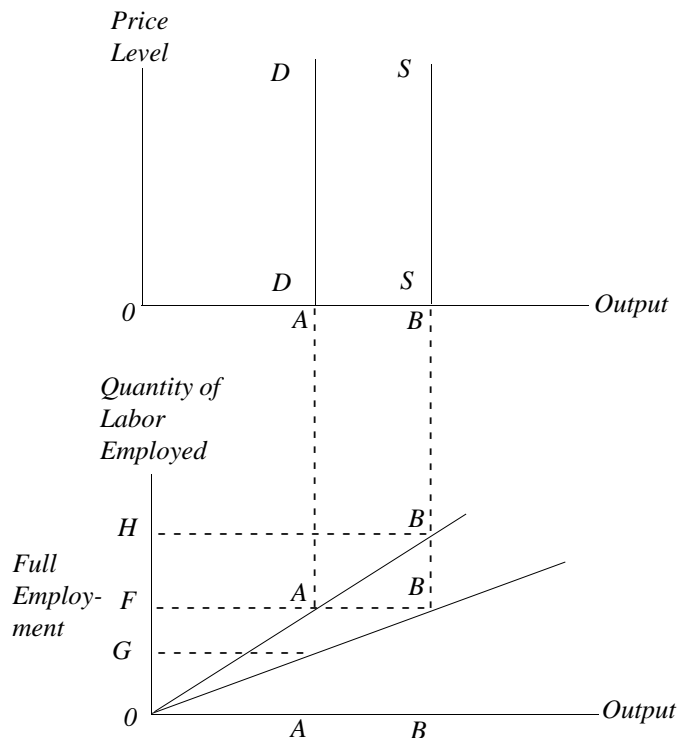

Consumptionist View of the Economic World.” There, in the upper portion of the figure, the consumptionists’ notion of a fixed aggregate demand is depicted by the vertical line *DD*, which claims that buyers are unwilling or unable to purchase a quantity of output greater than corresponds to point *A* on the horizontal axis. No matter how low prices go, the buyers allegedly will not buy more than an amount equal to *A*. Yet at the point of full employment, the economic system is capable of producing the larger quantity of output indicated by point *B* on the horizontal axis. The vertical line *SS*, drawn directly up from point *B*, shows aggregate supply at full employment. The extent to which *B* exceeds *A*, in other words the horizontal distance *AB*, is the measure of the alleged excess of supply over demand—the measure of alleged “overproduction.”

In sharpest contrast to consumptionism, productionism posits an aggregate demand curve for output that has no limit, that is capable of buying all that could ever be produced. This aggregate demand curve is shown in Figure 13–2. It is derived not only from the proposition that man’s need and desire for wealth have no fixed limit, but also from the quantity theory of money. In Figure 13–2, the demand curve *DD* represents a given total expenditure of money to buy products, corresponding to

a given total quantity of money in the economic system. The curve shows that the same expenditure of money can buy any volume of goods, depending only on the price level. At half the price level, it can buy twice the quantity of goods; at a fourth, eighth, or tenth of the price level, it can respectively buy four, eight, or ten times the quantity of goods; and so on, without limit. The curve is asymptotic—that is, it never crosses the horizontal or vertical axis. It is also unit elastic.⁹ (Of course, under a system of commodity money, to the extent that an aspect of increases in the production and supply of goods is an increase in the quantity of the commodity serving as money, the productionist aggregate demand curve shifts up and to the right. This diminishes the extent to which prices need to fall.)

While I will expand on the critique of the overproduction doctrine at considerable length in Part B of this chapter, it should already be obvious, in the very nature of the productionist aggregate demand curve and its foundations, that a general overproduction—an overproduction in the economic system as a whole—is an impossibility. It is also appropriate to note at this point the inherent absurdity of the overproduction doctrine. In blaming depressions and their accompanying impoverishment on overproduction, the doctrine implies that people

Figure 13–1
The Consumptionist View of the Economic World

cannot afford homes or apartments because they have built too many of them, that they cannot buy food because they have grown too much, that they cannot purchase cars or appliances because they have manufactured too many, in a word, that they are poor because they are rich.

2. Machinery and Unemployment

If one begins with the assumption that the buyers will buy just so much, then it follows that if now that given quantity of goods can be produced with less labor, because of the adoption of labor-saving machinery, then there will be correspondingly less work available for people to do, and thus that improvements in machinery cause unemployment. This is the essential nature of the belief that machinery causes unemployment—the process by which the conclusion is reached.

Figure 13–1 describes the consumptionist’s thought process in terms of diagrams. The lower diagram shows the relationship between the quantity of labor employed (and performed), which is measured on the vertical axis, and the quantity of output produced, which is measured on the horizontal axis. Given the state of technology and the quantity and quality of machinery and other means of production available per worker, the greater the quantity of labor that is employed, the greater is the quantity of output produced. Hence, the relationship is described by a line that slopes upward to the right.

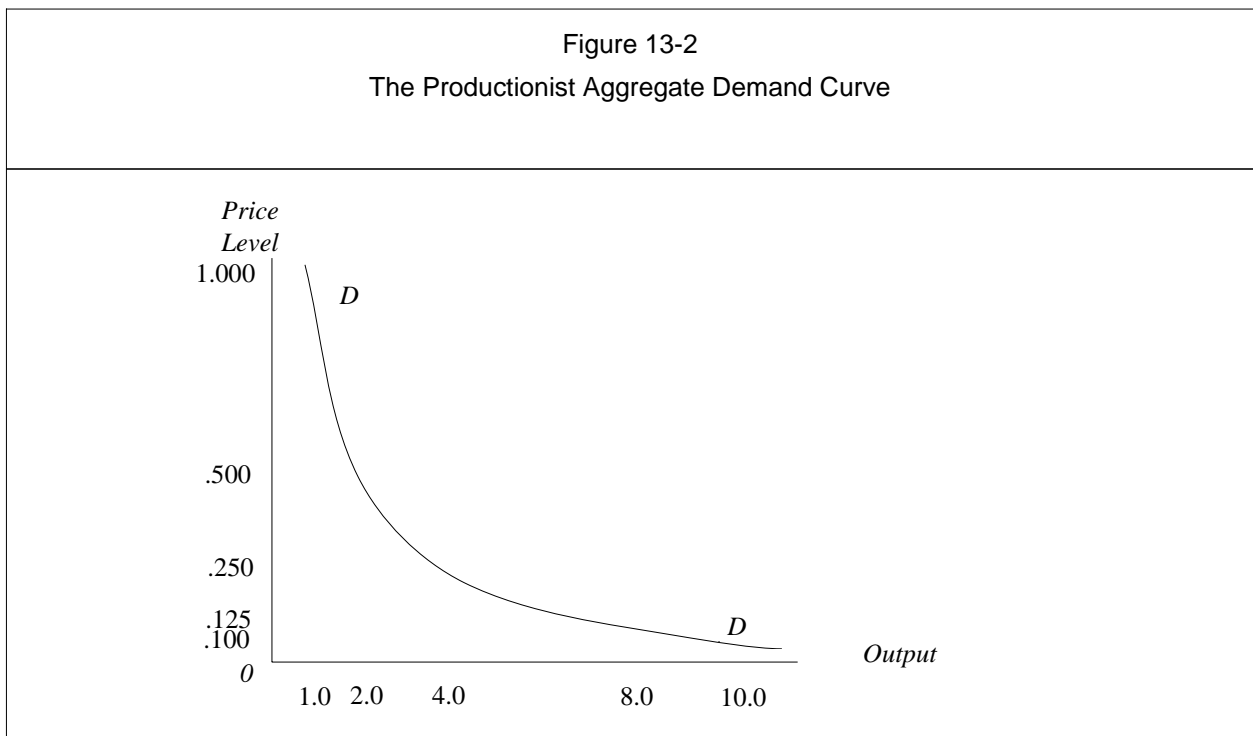

Initially, this relationship, which in contemporary eco-

nomics textbooks is rather pompously called a “production function,” is such that at the point of full employment—point *F* on the vertical axis—the output of the economic system is *A*, as indicated by the dashed line running from *F* to *A*. Looking upward, along the vertical dashed line running from *A* to the upper diagram, whose horizontal axis is exactly the same as that of the lower diagram, one sees that with an output of *A*, the aggregate supply initially does not exceed the allegedly fixed aggregate demand *DD* that is shown in the upper diagram. The aggregate supply *SS* corresponding to full employment under these conditions would supposedly lie directly beneath the aggregate demand *DD*, being perfectly concealed by it. Thus initially there is no alleged problem of “overproduction.”

Now, however, comes an improvement in machinery, as the result of which any given quantity of labor can produce a larger output than before. The effect of the improved machinery is described by a new “production function,” which is lower and further to the right than the original one, showing that any given quantity of labor now produces more than before, or, equivalently, that any given output can now be produced by less labor. At the point of full employment specifically, the same quantity of labor now produces the output *B* rather than *A*. This allegedly causes supply to exceed demand in the upper diagram, creating exactly the situation of alleged “overproduction” that we saw earlier. A continuation of the dashed line from *FA* to *FB*, and then a new vertical dashed line running upwards from point *B*, trace the new

Figure 13-2

The Productionist Aggregate Demand Curve

relationship between full employment and output.

Since businessmen will not continue to produce in excess of the demand, it is argued that production will fall back from B to the initial level of A . But now, because of the use of improved machinery and the consequent movement of the "production function" down and to the right, the output A is produced with a smaller quantity of labor than F . It is produced with quantity G of labor, which is the point found by locating A of output on the new, lower production function and then reading across to the vertical axis, as indicated by the dashed lines. FG is the measure of the unemployment supposedly caused by the use of improved machinery.

In just this way, the effect of improved machinery is allegedly to reduce the supply of work available for people to do. In effect, according to the consumptionists, because there is a need and desire for just so much output, there is a need for just so much work to produce that output, and to the extent that machinery can perform more of that work, there is correspondingly less work for people to do. Thus, supposedly, machinery causes unemployment by virtue of consuming part of the allegedly fixed amount of work to be done in the world corresponding to the allegedly fixed quantity of output that is demanded.

Now the actual effect of the adoption of labor-saving machinery, of course, is to cause not unemployment but a higher standard of living. In the economy as a whole, the effect of the adoption of labor-saving improvements is that the same number of workers end up producing a vastly increased quantity of goods and obtain the benefit of those goods in their capacity as consumers. Improvements in machinery of the labor-saving variety are an essential prerequisite of labor becoming available for increasing the production of goods previously considered luxuries and for working with improvements in machinery of the kind that make possible altogether new products.

There is no problem of a lack of demand for these additional goods. As we know from Chapter 2, the need and desire for goods always far outstrips the ability to produce goods and increases further as that ability increases. We also know that the productionist aggregate demand curve shows that even any given quantity of money and volume of spending is potentially capable of buying an unlimited quantity of goods at lower prices. If one visualizes the productionist aggregate demand curve being superimposed on the upper diagram in Figure 13-1, and taking the place of the consumptionist aggregate demand curve, then it is obvious that no matter how great the output becomes at the point of full employment, it will be demanded. At the same time, the standard of living of the average worker rises as the result of the adoption of labor-saving machinery, because the effect

of such machinery is always to increase the supply of goods relative to the supply of labor and thus to reduce prices relative to wage rates. This increases the buying power of wages and in this way the standard of living of the average wage earner.¹⁰

All of these propositions are confirmed by the leading facts of modern economic history. Since the beginning of the Industrial Revolution, the productivity of labor has increased by an order of magnitude of at least one hundred times. The unemployment rate is not on the order of 99 percent, as the argument that machinery causes unemployment implies, but is essentially no higher now than it was in the eighteenth century. In essence what has happened is simply that the same number of workers produces vastly more and enjoys a correspondingly higher standard of living. Indeed, not only do the same number of workers find employment, but an enormously larger number. Thanks to the rise in the productivity of labor, and thus the standard of living, achieved by the Industrial Revolution and its machinery, population figures have greatly increased. And essentially the same proportion of this much larger population finds employment as was the case before the start of the Industrial Revolution.

The basic effect of the adoption of machinery, or better machinery, on employment is simply that *the pattern of employment is changed*, in accordance with the change in the relative size of the various industries that results. Thus, insofar as labor-saving improvements are adopted in industries producing necessities, or any other goods of which relatively little more is wanted, employment in those industries falls. The leading example is agriculture. But in the very nature of the case, because less labor is needed in those industries and the funds which paid the wages of that labor can now be spared, funds are released for the employment of additional labor in industries producing other goods, previously beyond people's reach. Moreover, the fall in prices of the goods produced with less labor releases funds for a larger volume of consumer spending elsewhere in the economic system.

In cases in which the introduction of labor-saving machinery takes place in the production of goods previously considered luxuries and makes it possible for such goods to come within the reach of a large number of buyers with funds to spare from other purchases, the effect is to increase employment in the industry in which the labor-saving improvement is introduced. As previously pointed out, a good example of this kind is the automobile industry earlier in this century. In 1900, automobiles were as expensive as yachts are today, and only a handful of people could afford them. However, after productive geniuses such as Henry Ford and Alfred Sloan succeeded in radically reducing the quantity of labor required to produce an automobile, and thus brought

the automobile within reach of millions of buyers, the automobile industry became the largest employer of labor in the United States.¹¹ On a lesser scale, the same pattern occurred in the radio and television set industries and throughout the appliance industry. The video-tape recorder and personal computer industries provide more recent examples.

Because labor-saving machinery raises real wages, it places people in a position in which they can afford to choose additional leisure. Only in this, strictly *voluntary* sense, can it be said to reduce the total amount of employment. On the other hand, as I have indicated, it also enables a larger population to survive, whose members must work. In this sense, it can be said to increase the total amount of employment. Apart from the voluntary choice of additional leisure that it makes possible, and the increase in number of people alive and needing to work that it causes, machinery has no effect on the overall volume of employment, but only on the pattern in which the same total volume of employment is distributed among the different branches of industry. Its overwhelmingly outstanding effect is to raise the productivity of labor and the average standard of living.¹²

3. Alleged Inherent Group Conflicts Over Employment

As we have already seen in the argument against machinery, the notion of a fixed demand for goods implies the notion of a correspondingly fixed demand for the labor to produce them. If it were true that people desired to buy just so many goods, or could afford to buy just so many, then there would exist in the world just so much work that employers could offer—namely, the amount of work required to produce that limited quantity of goods, and nothing more. As we have seen, it is precisely on this basis that it is believed that machinery causes unemployment: it allegedly appropriates part of the limited stock of work to be done from people and transfers it to machines.

The notion of a limited demand for goods and a correspondingly limited amount of work to be done in producing them also shows up in the belief that there is an inherent conflict between men and women when both seek employment, and between whites and blacks, immigrants and natives, Protestants and Catholics, and all other such groups. Such statements as “married women shouldn’t work because they take away jobs from men,” or “immigration needs to be restricted so that native Americans can have jobs,” rest on the idea that there are only so many “jobs” to go around and that to the extent that more of them are held by the members of any one group, there are that many fewer of them remaining for

the members of other groups.

Figure 13–1 serves to depict the process of reaching such conclusions in much the same way as it depicts the process of reaching the conclusion that the use of machinery causes unemployment. Starting with the assumption that point *F* on the vertical axis in the lower diagram represents full employment and results in an output of *A* on the prevailing “production function,” it is now only necessary to assume that because of the entry of additional people into the labor market, the point at which full employment exists rises from *F* to *H*. If *H* marked the actual level of employment, then output would once again be *B*, this time on the original “production function.” (This becomes apparent if one follows the dashes from point *H* on the vertical axis over to the original production function. The corresponding output will lie at the same point as in the case when improvements in machinery moved the production function to the right.) In the upper diagram of Figure 13–1, this would once again mean an alleged overproduction measured by the excess of *B* over *A*. Once again, production would supposedly have to return to *A* so that supply ceased to exceed demand. Thus, the volume of employment would supposedly return to *F*, the old full employment point. With employment once again at *F*, the inescapable implication is that for everyone in the group of new workers, *FH*, who has gained employment, someone else in the original group, *OF*, has lost employment.

(Exactly the same analysis, it should be noted, applies to the case of workers seeking to increase their hours of work. They too allegedly deprive others of work. They allegedly appropriate more than their “fair share” of that allegedly scarce commodity “work.”)

The existence of a limitless need and desire for wealth obviously precludes the existence of any fundamental conflict among groups for limited job opportunities. Just as in the case of machinery, if the productionist aggregate demand curve is substituted for the consumptionist aggregate demand curve, then once again it is clear that the market can accommodate all the additional output that can be produced by any additional number of workers. And this too is confirmed by the leading facts of modern economic history. Just as the hundredfold or more increase in the productivity of labor has not resulted in 99 percent unemployment, or any increase in the unemployment rate whatever, consumptionism to the contrary notwithstanding, so the vast increase in the number of people seeking employment that the Industrial Revolution and its machinery have made possible has not resulted in any displacement of workers. Far more people are alive. Far more people seek work. And far more people work. It is that simple because there is need and desire for all the output that any number of workers can

produce, and any given quantity of money and volume of spending is capable of buying that output, however large.¹³ The same principles, of course, apply to any increase in the hours of work that individuals might wish to perform, though as a rule individuals choose to work less as the result of a rising productivity of labor and the consequent rise in living standards.

Furthermore, as we have seen, under capitalism the effect of the employment of a larger number of workers is to raise the real income of the average worker by virtue of extending the division of labor and enabling the occupations concerned with the discovery and application of new knowledge to be carried on, on a larger scale, thereby raising the productivity of labor.¹⁴ In Part C of this chapter, we will see that even though the achievement of full employment may entail a fall in the average level of money wage rates, the effect is still to raise the average level of *real* wage rates (that is, what the money wage rates can actually buy) and thus the actual standard of living of the average worker. In the next chapter, we will see that the effect of married women working is simply to raise the real income of their families.¹⁵

While there is no foundation for group conflicts over employment under capitalism and a free labor market, it is important to realize that such conflicts can be artificially created by means of government interference that sets wage rates too high and thereby creates a problem of permanent mass unemployment.¹⁶ In conditions in which the overall total number of jobs is artificially limited by making it impossible for wage rates to fall and thus increase the quantity of labor demanded, it is true that the members of any one group can gain employment only at the expense of the employment of members of other groups. The obvious solution, of course, is not to try to prevent the competition of members of other groups but to abolish the government's interference with wage rates.

4. Make-Work Schemes and Spread-the-Work Schemes

The belief in a scarcity of work to be done in the world leads to the belief that what it is necessary to make is not more goods (that, it is claimed, only causes unemployment) but *more work*. According to the supporters of this idea, while scientists and inventors and greedy businessmen are off plundering the community's precious stock of work to be done, with their ceaseless striving for improvements in efficiency, union leaders, government officials, and every good union man must perform the vital function of making work—by, for example, respectively requiring the employment of electricians whose full time jobs consist of nothing more than turning the

lights on and off once a day, by employing people in public works projects, and by doing things more slowly and less efficiently whenever possible.

The effect of "making work" is obviously to hold down the standard of living by reducing output per worker. Indeed, the effect of make-work projects is likely to be not that the same output is produced by a larger number of workers, but that a smaller output is produced by the same number of workers. For there is nothing present in any make-work scheme that increases the overall quantity of labor demanded. That would require lower wage rates—given the quantity of money and volume of spending in the economic system. Thus, the effect of make-work schemes is that for every extra useless worker who is employed and adds little or nothing to output, some other, far more productive worker is forced into unemployment. In other words, the effect of make-work schemes is that less-efficient workers take the place of more-efficient workers, less is produced, and the standard of living is reduced. (It should be realized, of course, that the reduction in employment can be shifted to other industries. Thus if a plumbing repair is made to use the services of an unnecessary tile setter, say, the effect is not that the tile setter takes the place of the plumber. He may take the place of an auto worker, a travel agent, a farmer—a worker anywhere in the economic system where demand is now less because funds have been tied up in paying the wages of the tile setter and in buying the artificially more expensive product that is the result of his employment.)

Somewhat similar to make-work schemes, and put forward in response to the same alleged problem of a scarcity of work to be done in the world, are spread-the-work schemes. Here the existence of a given amount of work to be done is taken for granted and the attempt is made to "spread it around"—"fairly." Thus if the average work week were forty hours and at the same time one worker in four were unemployed, the advocates of spread-the-work would call for a reduction in the work week to thirty hours, in the belief that then everyone could be employed at three-quarters time, rather than three-fourths of the workers at full time.

While the effect of make-work schemes is to shift the burden of unemployment to workers who are presently employed in an efficient manner, in order to make way for workers who will be employed inefficiently, the effect of spread-the-work schemes is not only likely to be very similar, but also very likely to increase the overall amount of unemployment as well, depending on what happens to wage rates.¹⁷

If no attempt is made to raise hourly wage rates, then those who already have full-time jobs must suffer a reduction in their weekly wages to whatever extent their

hours are reduced as the result of spreading the work. More likely than not, at the same time some decline in production will occur and some rise in unit costs and prices will take place, even though the hours worked in the economic system as a whole are the same as before. This result is likely because the workers who were without jobs were likely to have been less efficient than the workers with jobs, inasmuch as employers, as far as they have any choice in the matter, prefer to let go of their poorer workers before their better ones. Thus, by and large, it is the better workers who were able to retain their jobs and the poorer workers who were unemployed. To this extent, “spreading the work” entails substituting hours worked by less efficient workers for hours worked by more efficient workers. In this way, it reduces overall output and raises production costs and prices, even if it leaves the total hours worked the same.

However, the total number of hours worked is unlikely to remain the same. This is because in an effort to compensate the workers who already have jobs and now must accept shorter hours as a result of spreading the work, the attempt will almost certainly be made to raise hourly wage rates. To the extent the attempt succeeds, the total number of hours of labor demanded falls. Indeed, in the face of a fixed aggregate monetary demand for labor—fixed total payrolls in the economic system—which it is reasonable to assume as a central case if the quantity of money and volume of spending are fixed), *the decrease in hours demanded is in inverse proportion to the rise in hourly wage rates*. Thus, in the case of a reduction in the work week from forty hours to thirty hours, accompanied by a fully compensating rise in average hourly wage rates in the ratio of four to three, the effect would be that total hours demanded and worked in the economic system would fall in the ratio of three to four, that is, by an additional 25 percent!

This would mean that to whatever extent some of the previously unemployed obtained jobs, the effect would be that those who already had jobs would lose them outright. The latter would not merely work thirty hours instead of forty: in order to make room for the unemployed, they themselves would be thrown into unemployment. Indeed, in these circumstances, the previously unemployed could find employment *only* to the extent that those who had jobs lost them or at least reduced their hours below thirty per week. This is because the rise in hourly pay to compensate for the shortening of hours totally nullifies any ability of shorter hours to serve as the basis for spreading the work. Thus any employment gained by the previously unemployed must come at the expense of a further reduction in the employment of those who presently are employed.

5. War and Government Spending

According to consumptionism, war has a variety of economically beneficial consequences that promote employment. It creates an enormous additional need for wealth during the war—in the form of tanks, planes, ammunition, and so on. In addition, the destruction it entails creates the need for replacing what is destroyed. And, finally, the cutback in normal civilian production that takes place during the war supposedly operates to create a kind of bank account for postwar demand: the limited need and desire for goods that people would normally have, and which cannot be satisfied during the war, supposedly accumulates and is available after the war to help prolong the alleged prosperity the war brings, by providing for the release of “pent-up” demand. In all these ways, according to consumptionism, war serves to move the allegedly fixed aggregate demand curve of Figure 13–1 to the right, and thus makes possible greater employment.

An aspect of these absurdities that is worth pointing out is that the consumptionist values the *absence* of wealth rather than wealth. For example, after World War II, he believed that the relative absence of houses, automobiles, and refrigerators in Europe was an asset of the European economy because it represented a large supply of unused consumer desire, thereby supposedly ensuring a strong consumer demand. By the same token, he believed that the relative abundance of these goods in the United States was a liability of the American economy because it represented a depleted supply of consumer desire, thereby supposedly ensuring only a weak consumer demand. Prosperity depends on the absence of wealth, and poverty follows from its abundance, the consumptionist concludes, because that priceless commodity, consumer desire, more limited in supply than diamonds, is produced by the absence and consumed by the presence of wealth.

In contrast to all such absurdities, productionism recognizes that the need for wealth is always superabundant and thus that the last thing in the world that is necessary is to create more need for wealth by destroying existing wealth. It is wealth, not the need for wealth, that must be created, and this is what war wastes and destroys. The actual economic effect of war is to divert production from civilian goods to war goods, which have no economic benefit. It is also to cause people to work longer and harder, and people who otherwise would not have found it necessary to work, such as many housewives and teenagers, to go to work—all in an effort to offset the drop in the standard of living that the diversion of output to the war effort causes. Similarly, the postwar replacement of wealth needlessly destroyed in war is at the

expense of new and additional wealth that otherwise could have been enjoyed in addition to the wealth needlessly destroyed, and at the expense of leisure that people could otherwise have afforded to choose. The same is true of the wartime need to postpone the production of civilian goods. Had the production of those goods not had to be postponed, new and additional wealth could have been produced and enjoyed in subsequent years, and people could also have afforded to choose more leisure.

Nor does war promote prosperity by means of the postwar application of scientific or technological advances made in connection with the war effort. Like the output of war goods, which are at the expense of the output of civilian goods, the scientific and technological advances made in connection with war are at the expense of the advances that would have taken place had the labor of scientists and engineers not had to be diverted from peacetime pursuits to the war effort. While the most that is gained from the war effort are some derivative peacetime applications—mere by-products of the war effort—what is lost are the kinds of advances that would have resulted from the full, focused application of scientific and engineering talent to peacetime advances. In the nature of the case, the loss is greater than the gain, and thus, on net balance, war detracts from scientific and technological progress. Indeed, as we have already seen, so far from it being the case that a focus on the technology of war can serve as the foundation for technology of value to the lives of human beings, that the reverse is true. Those countries which have been free to devote their efforts to improving human life and well-being, such as the United States (at least for most of its history), have, as a by-product of their peaceful, civilian scientific and technological pursuits, developed the foundation for far more powerful military technology than countries bent on war and aggression.¹⁸

Finally, war does not promote prosperity by making possible the replacement of factories and machines that have been destroyed, with more advanced factories and machines.¹⁹ The physical foundation for the construction of new factories and machines is existing factories and machines. The destruction of factories and machines destroys the physical ability to produce newer, more advanced factories and machines.

These propositions are in no way contradicted by the postwar experience of Germany and Japan. The physical ability of postwar Germany and Japan to rebuild was enormously facilitated by the fact that the factories and machines of the United States had escaped physical destruction. Had the United States been bombed to the extent that Germany and Japan had been bombed, the rebuilding would have taken many more years, if, in-

deed, it would have been possible at all. The ability of these countries to recover was also facilitated to the extent that their existing factories and machines had escaped damage and thus were available to serve in production, including not only the production of more advanced factories and machines but also goods to exchange for more advanced factories and machines.

The fact that in the years since World War II, Germany and Japan have in many cases built factories that are more modern than those used in the United States does not at all prove how fortunate they were to have been the scene of massive bombing raids and how unfortunate we were to have escaped bombing. Their success is the result of the fact that starting with whatever capital goods were available to them, they produced substantially as much as they could, and devoted a proportion of their productive efforts to the production of capital goods that was more than sufficient to replace the capital goods used up in production. This increased the capital goods at their disposal and enabled them to increase their production further. And out of the larger production, they again devoted a proportion sufficient more than to replace the capital goods consumed in production, and by a wide margin. Repeating this process over decades is the essential explanation of their great economic success.

Starting with far more capital goods, the United States was in a much better position to add further to its supply of capital goods than Germany or Japan. But the destructive policies of its government prevented it from doing so. Government policies such as confiscatory taxation (especially of profits and interest), chronic budget deficits, inflation of the money supply, prolabor legislation, and ever growing regulation in general, have stood in the way of saving and capital accumulation to a much greater extent in the postwar United States than in postwar Germany or Japan. This is the essential reason for their much more rapid rate of economic progress since World War II.²⁰

It is true that World War II was accompanied by the elimination of mass unemployment in the United States. Part C of this chapter will explain why this was the case, in a way that is perfectly consistent with the philosophy of productionism. It will show that it was not the war as such that brought about full employment, nor any increase in the need for wealth that is associated with war, but a change in the relationship between wage rates and prices on the one side and the quantity of money and volume of spending in the economic system, on the other. It will show how the necessary change in this relationship, and thus full employment, could have been achieved without the war, and how government intervention in the labor market prevented its achievement. It will also show that despite the existence of full employment, and the

illusion of prosperity, the war was actually a period of impoverishment far worse than the worst years of the depression of the 1930s. It will show that full employment with prosperity was achieved only after the war ended, and the labor and capital that had been devoted to the war effort once again became available for the production of peacetime, civilian goods.

The fact that war is economically destructive does not mean, of course, that there is no legitimate basis for war. When war is necessary for the defense of individual freedom, it is justified. What must never be forgotten is simply that even when it is justified, war is always a great expense, not a source of prosperity.

Consumptionists see additional peacetime government spending, whether for public works or for social welfare, as a source of prosperity comparable to war, but without entailing loss of human life. Such spending, they believe, is as beneficial to employment as would be a policy of calling in the artillery or airforce to destroy buildings after they had been evacuated. For it too allegedly increases the demand for goods and thus the need for labor, by virtue of the government performing the supposedly valuable service of exchanging its consumption for the people's products. In view of the fact that until recently, the enemy in any war we were likely to become involved in would directly or indirectly have been the Soviet Union, whose social system even now still evokes substantial support among intellectuals, this alleged method of promoting prosperity has become much more favored than war.

Of course, since there is in fact no lack of demand for goods or need for labor, the actual effect of government spending to promote employment is to divert production from the goods and services that people voluntarily choose to buy, to goods and services that they do not value sufficiently to buy. In the process, it also reduces their overall ability to produce. This last occurs as the result both of reducing their incentive to work and produce, through higher taxes to pay for the additional spending, and their freedom to produce, through a growing array of regulations enforced by many of those added to the government's payroll. Thus, production is diverted away from goods and services of value to taxpayers to such things as the production of goods and services for welfare recipients, the provision of "education" to other people's children, and the production of farm products to rot or to be given away. In addition, it is diverted to providing for the wants of millions of government employees whose function is nothing other than to restrict the freedom of the taxpayers.

In the nature of the case, all government spending inspired by consumptionism must be highly wasteful.

This follows from the fact that its essential purpose is not the achievement of any positive value in exchange for the expenditure, but merely to promote employment. If the government desires something as a positive value, such as a new courthouse or police station, then, just like any other buyer, it would want to obtain the best product it could for as little money as possible. In such a case, the government would implicitly want its product to be produced as efficiently as possible, as the basis for obtaining it for as little money as possible. For all practical purposes, this would mean that it would want its product produced with as little labor as possible, inasmuch as that is the essential nature of efficient production. However, if the government's goal is to increase spending and employment, then what it wants is not the most and best product for the least money, produced with the least amount of labor possible, but a product for the *most* money, produced with the greatest amount of labor possible. In fact, the product itself altogether ceases to matter. It can be no product at all or the most absurd product, such as pyramids—as Keynes would be among the first to admit. For the value, according to consumptionism, is not the product gained but the expenditure made and the employment that is allegedly created.²¹

Of course, all of the wasteful and destructive economic consequences of war and government spending can be reversed by the coming of peace and by the dismantling of the government programs. (The dismantling of the civilian programs, of course, can be undertaken at any time.) The effect would be a reduction in the labor and capital devoted to producing for the government's purposes, or for the purposes of those to whom the government gives or pays money, and an equivalent increase in the labor and capital devoted to producing for the purposes of private citizens. Indeed, insofar as the reduction in government spending took the form of a reduction in welfare payments to the able bodied, the effect would be an increase in the number of people working and an increase in the total volume of goods produced. This is because the former welfare recipients would now have to support themselves instead of being supported by others. An increase in the total volume of goods produced would also be the effect insofar as military personnel and other government employees re-joined the private, civilian labor force and thus the ranks of producers' labor, in contrast to their present status of consumers' labor.²² In addition, in the case of the firing of government personnel who presently carry out the regulations hampering productive activity, the further effect would be that the efforts of the citizens would be made correspondingly more productive.

Ironically, it follows from these facts that, given some time to adjust, the effect would be that even the former

welfare recipients and government employees would come out far ahead of where they were when they were on welfare or working for the government. For once they learned the habit of working, or of working in the far more efficient, competitive conditions of private business rather than in the sheltered environment of the government, and doing so, moreover, in the face of a reduced burden of taxation and regulation, they would produce and enjoy far more than they can presently wring from others by force.

6. Population Growth and Demand

In addition to war and government spending, consumptionism claims that a larger number of people, each with his or her limited quota of needs and desires, increases the total demand for goods and thus helps to eliminate the alleged excess of the ability to produce over the need and desire to consume. The existence of a larger number of people, the consumptionist tells businessmen, makes it possible for business to find someone upon whom to unload its otherwise superfluous goods. Business will prosper because its supply of goods will find a counterpart in an adequate supply of desire for goods. These beliefs are the foundation for the talk about “baby booms” and the additional demand for goods of all kinds that is automatically supposed to result from them.

Of course, when these alleged economic benefits of the larger population are put forward, there is no discussion of the additional people entering the labor market and seeking employment. The consumptionist premise, which leads to the larger population being viewed favorably from the perspective of its effects on demand, must lead to it being viewed unfavorably from the perspective of its effects on the supply of labor. For, as we have seen, it follows on the consumptionist premise, that to the extent that the larger population’s members gain jobs, correspondingly fewer additional jobs are available for others. Thus, what is supposed to be the cause of prosperity here, according to consumptionism, is that the additional people exist *only as consumers*, not as producers—that is, that they exist as parasites. *That* will be their alleged contribution to employment and prosperity. In that way, they will supply the need for goods, which is allegedly scarce, but not goods, which are allegedly superabundant.

In opposition to these absurdities, the productionist recognizes that the birth and upbringing of children always constitutes an expense to the parents. In raising children, the parents must spend money on them which they otherwise would have spent on themselves. Of course, the parents may, and hopefully will, consider the money better and more enjoyably spent on their children;

but still, it is an expense. And if they have a large enough number of children, they will be reduced to poverty. This is a fact that anyone can observe in any large family that does not possess a correspondingly large income. The presence of children does not make the parents spend more than they otherwise would have, but only spend *differently* than they otherwise would have. They buy baby food, toys, and bicycles instead of more restaurant meals, a better car, or costlier vacations. There is no stimulus given to production. Production is merely differently directed, to the different distribution of demand.

In reality, the only increase in production that could take place would be as the result of the parents working longer or harder to be able to support their children while still maintaining their own previous standard of living. Furthermore, when the children grow up, the additional market that they are supposed to constitute for houses and automobiles and the like will materialize only to the extent that they themselves are able to produce the equivalent of these things and thereby earn the money with which to purchase them. Thus it will only be by virtue of their production, and not by virtue of their desire to consume, that they will be able to constitute an additional market.

7. Imperialism and Foreign Trade

The same considerations that make the consumptionist believe that a larger population at home is desirable, by virtue of its possession of a larger stock of needs and desires for goods, make him believe that it is desirable to secure the needs and desires of the vast, impoverished populations of backward foreign countries. To the consumptionist, such countries appear as virtual treasure houses of unused consumer desires. He counts the numbers of their inhabitants and the lack of goods of each person, and arrives at what he considers to be staggering sources of demand.

Such ideas undoubtedly influenced the economically ignorant politicians of many European countries before World War I, particularly those of Germany, in embarking upon policies of imperialism and colonial conquest.²³ Instead of denouncing the economic ignorance of those politicians, many historians accept exactly the same false premises of consumptionism, and thus routinely explain World War I as having been caused by conflicts among the advanced countries of Western Europe for so-called markets in the backward nations. According to such historians, each of the European powers allegedly had a problem of overproduction at home and was thus in need of foreign markets as an outlet for its allegedly surplus goods. So valuable were these alleged foreign markets supposed to be to the European countries, that, according

to such historians, it is understandable that they were considered worth fighting for. More recently, the same logic was applied to the United States' involvement in Vietnam. It was claimed that we were there in order to be sure of having access to the vast "markets" of Southeast Asia.

Contrary to consumptionism and the ignorant politicians and historians that it influences, hordes of impoverished beggars do not constitute markets. Countries, and individuals, constitute markets not to the extent that they have needs and desires for goods, but to the extent that they produce and supply goods. Only to this extent are they in a position to earn the wherewithal to purchase goods and thus to constitute markets. It is for this reason that the United States and Japan are vastly greater markets than India and China, as I previously pointed out, and that Beverly Hills is a vastly greater market than Watts.

It should be realized that the same problem arises for the consumptionist in connection with the policy of imperialism, and foreign trade in general, as arises in connection with a larger population at home. Namely, the consumptionist (and imperialist) values foreign countries only as sources of alleged demand, by which, of course, he means needs and desires. At the same time, he fears them as sources of supply. To the extent that they become sources of supply, such as Hong Kong, Taiwan, South Korea, and Japan, he fears them as depriving domestic producers of markets and thus workers at home of jobs. The consumptionist believes that the gains from foreign trade are in the exports, not the imports. His view of a beneficial relationship with foreign countries is that they should provide us with their needs and desires, so as to provide an outlet for our allegedly excess goods, not that they should provide us with goods. He believes that the object of foreign trade should be to have the maximum possible excess of exports over imports. His ideal is that his country should only export and not import at all, or import only to the extent that doing so is vitally necessary or contributes to the production of a more than compensating quantity of additional exports.²⁴ Obviously, the notion that an excess of exports over imports constitutes a "favorable balance of trade" is entirely consistent with consumptionism and draws much of its support from it.²⁵

Thus, the idea of the consumptionist and the imperialist is that a country benefits by virtue of actually *giving its goods away for free*—by working and sending them out and by receiving back as little as possible. And more, that this privilege is worth fighting for. Indeed, so perverse is the consumptionist view of things that it leads to absurdity heaped upon absurdity. By the logic of those who hold it, the military presence of the United States in Vietnam was to be explained on the grounds that the

people of Southeast Asia were too clever to be willing to accept our goods for free. We allegedly had to use force to make them accept such an arrangement, allegedly so harmful to them and so beneficial to ourselves. According to the consumptionist, the privilege of supplying impoverished beggars—that is, of working for nothing—is so valuable that if it is not actually worth dying for, it is at least understandable why it should appear to be so, to those not restrained from the pursuit of material self-interest by the possession of more noble sensibilities. This is what consumptionist historians and moralists believe.

It needs to be pointed out that the actual benefit of international trade is in the imports, not the exports. The citizens of a country gain in the conduct of international trade by virtue of the fact that the goods and services brought in by international trade surpass the goods and services that the labor and capital employed in producing exports could produce for the domestic market. Thus, to recall the example of automobiles and coffee from Chapter 9, the United States gains in its trade with Brazil by virtue of obtaining more coffee through the production of automobiles for export than it could by using the same amount of labor to produce coffee. At the same time, Brazil gains by virtue of obtaining automobiles and other manufactured goods in far greater quantity through the export of coffee than it could obtain by attempting to use the same amount of labor to produce such goods in Brazil. Or, equivalently, the countries gain by obtaining the same amount of goods with the use of less labor, and thus have labor left over to produce more of other things.²⁶

International trade does not cause unemployment but, like machinery, a higher productivity of labor and standard of living. As in the case of machinery, the effect on employment is merely a change in the pattern of employment. Fewer workers are employed in the industries in which foreigners enjoy a comparative advantage and hence in which the country imports, and more workers are employed in the industries in which the given country enjoys a comparative advantage and hence in which it exports.²⁷ Overall, the effect is the same volume of employment but more goods.

8. Parasitism as an Alleged Source of Gain to Its Victims

The consumptionist's views on the allegedly beneficial effects of war, government spending, population growth, and imperialism rest on the idea that one benefits producers by the mere fact of consuming their products. This gives the producers the work to do of making possible one's consumption. Such an idea is obviously

absurd. Only the use of money lends it the least semblance of plausibility. If it were true, then every slave who ever lived should have cherished his master's every whim the satisfaction of which required of him more work. A slave should have been grateful if his master desired a larger house, an improved road, more food, more parties, and so on; for the provision of the means of satisfying these desires would have given him correspondingly more work to do.

The belief that the consumption of the government, or of private nonproducing consumers at home or abroad, benefits and helps to support the economic system is on precisely the same footing as the belief that the consumption of the master benefits and supports the slave. It is a belief the absurdity of which is matched only by the injustice it makes possible. It is the means by which parasitical pressure groups, employing the government as an agent of plunder, seek to delude their victims into believing that they are benefitted and supported by those who take their products and give them nothing in return.

The only economic benefit that one can give to producers consists in the exchange of one's own products or services for their products or services. It is by means of what one produces and offers in exchange that one benefits producers, not by means of what one consumes. To the extent that one consumes the products or services of others without offering products or services in exchange, one consumes at their expense.

The use of money makes this point somewhat less obvious but no less true. Where money is employed, producers do not exchange goods and services directly, but indirectly. The buyer exchanges money for the goods of a seller. The seller then exchanges the money for the goods of other sellers, and so on. But every buyer in the series must either himself have offered goods and services for sale equivalent to those he purchases, or have obtained his funds from someone else who has done so.

The fact that in a monetary economy everyone measures his benefit by the amount of money he obtains in exchange for his goods or services is interpreted by the consumptionist to imply that the mere spending of money is a virtue and that economic prosperity is to be found through the creation and spending of new and additional money—i.e., by a policy of inflation.

The fact is that for everyone who spends newly created money and thus obtains goods and services without having produced equivalent goods and services, there must be others who suffer a corresponding loss. Their loss takes the form either of a depletion of their capital, a diminution of their consumption, or a lack of reward for the added labor they perform—a loss precisely equal to the goods and services obtained by the buyers who do not produce.

The consumptionist's advocacy of consumption by those who do not produce, to ensure the prosperity of those who do, is a pathological response to an economic world which the consumptionist imagines to be ruled by pathology. The consumptionist has always before him the pathology of the miser. His reasoning is dominated by the thought of cash hoarding. He believes that one part of mankind is driven by a purposeless passion for work without reward, which requires for its fulfillment the existence of another part of mankind eager to accept reward without work. This is the meaning of the belief that one set of men desire only to produce and sell, but not to buy and consume, and the inference that what is required is another set of men who will buy and consume, but who will not produce and sell. In the consumptionist's world, the producers are imagined to produce merely for the sake of obtaining money. The consumptionist stands ready to supply them with money in exchange for their goods—he proposes either to take from them the money he believes they would not spend, and then have someone else spend it, or to print more money and allow them to accumulate paper as others acquire their goods.

Hoarding is not the only phenomenon upon which the consumptionist seizes. Where nothing in reality will serve, the consumptionist is highly adept at bringing forth totally imaginary causes of economic catastrophe. Invariably, the solution advanced is consumption by those who have not produced, for the sake of those who have. Always, the goal is to demonstrate the necessity and beneficial effect of parasitism—to present parasitism as a source of prosperity to its victims. This is the meaning of his beliefs about the allegedly beneficial effects of make-work schemes, war and government spending, a growth in the population of idle consumers, and fighting for the privilege of supplying beggars around the world.²⁸

9. Advertising as Allegedly Fraudulent but Economically Beneficial

The consumptionist views advertising as attempting to induce people to buy goods for which they have no real need. At the same time, precisely on the basis of this belief, he regards advertising as a method of stimulating demand in the economic system and thus helping to overcome the alleged deficiency of demand.

The fact is that advertising does not create consumer desire where no desire for additional goods would otherwise have existed. It is not the case that, in the absence of advertising, people would be at a loss as to how to spend their money. Advertising is not required, and would not be sufficient, to rouse vegetables into men. What

advertising does, by making people more aware of the alternatives available to them, is lead them to consume differently and in a better way than they otherwise would have. Advertising is a tool of competition, and, as such, for every competing product whose sale is increased by it, there is another competing product whose sale is decreased by it. The only exceptions are insofar as advertising contributes to the increase in production—for example, by making people aware of the existence of products which they judge to be important enough to be worth expending extra effort to earn the money to purchase. Such cases are a further illustration of the fact that it is only the increase in aggregate supply that increases aggregate demand.

The consumptionist's attitude toward advertising brings into clear relief some further corollaries and implications of his basic premise. His estimate of advertising, like that of war and destruction, is ambivalent, and necessarily so. On the one hand, he approves of it, on the grounds that by creating consumer desires, it creates the work required to satisfy those desires. However, this very belief, that advertising creates desires where absolutely no desires would otherwise exist, also makes him condemn advertising. For if it were true that, in the absence of advertising, men would be perfectly content with very little, the desires created by advertising must appear to be only superficial and basically unnecessary and unnatural.

And this, of course, as previously explained, is precisely how the consumptionist regards such desires. In his eyes, all desires men have for goods, beyond what is necessary to make possible bare physical survival and a vegetative existence, represent an unnatural taste for "luxuries." These desires the consumptionist considers to be inherently unimportant. Their only justification is the creation of work. The consumptionist's conception of the greater part of economic activity, therefore, is that it represents senseless motion, with deceit and deception required to make people desire goods for which they have no need, in order to enable them to pass their lives in the production of those very same goods.²⁹

In reality, of course, people's desire for "luxuries" is necessary and natural, for it is nothing but the desire to satisfy their inherent needs (including the need for aesthetic satisfaction) in an ever more improved way. It is from the importance that attaches to the satisfaction of the desire for "luxuries" that the importance of the work required to produce them is derived, and not vice versa. Indeed, however paradoxical it may appear, it is only from the perspective of productionism that one can understand the actual importance of consumer desires—namely, as the ever-present end and purpose of all production, not as a means serving production absurdly regarded as an end in itself.

10. Misconception of the Value of Technological Progress

Just as he believes in the need to create uses for an expanding supply of consumers' goods, so the consumptionist believes there is a problem of finding "investment outlets" for an expanding supply of capital goods. Here he looks to technological progress as providing a possible solution to this alleged problem. Its contribution is supposed to be the enlargement of the "supply of investment outlets" or "investment opportunities."

The fact is that the value of technological progress does not lie in the creation of "investment outlets" or "investment opportunities" for an expanding supply of capital goods. If the concept of capital goods is properly understood, as denoting all goods that the buyer employs for the purpose of producing goods that are to be sold, then, as has already been shown in Chapter 2, it is clear that there is no such thing as a lack of "investment outlets" or "investment opportunities" for capital goods. So long as more or improved consumers' goods are desired, there is need of a larger supply of capital goods. As shown, capital goods are scarce both in their horizontal and vertical dimensions.³⁰

For example, ten million automobiles of a given quality require the employment of twice the quantity of capital goods—twice the quantity of steel, glass, tires, paint, engines, and machinery—in their production as do five million such automobiles. If the quality of the automobiles is to be improved, or if the efficiency of their production is to be increased by the adoption of more capital-intensive methods of production, then a larger quantity of capital goods is required for the production of the same number of automobiles. For example, a given number of cars of Chevrolet quality, with their greater number of accessories and larger size and greater need for materials, require a larger quantity of capital goods in their production than the same number of cars of Volkswagen quality; the same number of cars of Cadillac quality require still a larger supply of capital goods; and the same number of cars of Rolls-Royce quality require yet an even more enlarged supply. Greater capital intensiveness is entailed not only in shifting from such lower-quality models to such higher-quality models, but also insofar as more capital-intensive methods of production are to replace less capital-intensive methods of production in the manufacture of any of these given models. To this extent, too, a larger supply of capital goods is required.

The identical principle applies to houses of different size and quality. A given quantity of eight-room houses of a given quality requires the employment of a larger supply of capital goods than the same number of seven-

room houses of the same quality. A given number of brick houses requires a larger supply of capital goods than the same number of wooden houses of the same size; the bricks or any more expensive material constitute a larger supply of capital goods because a larger quantity of labor is required to produce them. The principle applies to food and clothing, to furniture and appliances, to every good. So long as more of any consumers' good is desired, so long as not every consumers' good that is produced is of the very best-known quality, and produced by the most capital-intensive methods, there is a need for a larger supply of capital goods.

It is not the case that in the absence of technological progress, the supply of capital goods would continue to expand but find no "investment outlets." It is not the case that what we have to fear from a lack of technological progress is a flood of capital goods surpassing every possible use for capital goods, and that then we will be at a loss as to how to employ our expanding supply of capital goods. Before such a situation could exist, every car produced would have to be the equivalent of the finest-known-model Rolls Royce; every house would have to be a palatial mansion; every suit of clothes would have to be fit for the Prince of Wales. This is because so long as any such possibilities remained unmet, there would be a need for the additional capital goods that would enable them to be met. Before such a situation could exist, capital intensiveness would have to be carried to its utmost limits in terms of reducing costs and improving the quality of goods in every respect. Among other things, this would mean that every known machine that can save labor would be in use in every possible case, that bridges and tunnels would eliminate every major detour across land or around water, that the roads and railroads would be straight and level, and that all major inland cities technologically capable of having access to the sea would have it. Clearly, whatever problems the world may face, such a situation is not one of them. Clearly, whatever our worries may be, such a situation deserves no place among them. On the contrary, what we have to fear from a lack of technological progress is not that we will be overrun with a supply of capital goods that surpasses all worthwhile uses for capital goods and that we shall then be at a loss for what to do with our still expanding supply of capital goods, but that we will *not* have an increase in the supply of capital goods, that we will not be able to exploit any considerable portion of the virtually limitless "investment outlets" that already exist, within the framework of known technology.

The value of technological progress consists in the fact that it enables us to *obtain* a larger supply of capital goods, and not that it solves the problem of what to do with a larger supply.³¹ The technological advances that

made possible the canal building and railroad building of the nineteenth century and the development of the steel industry were valuable, not because they absorbed capital goods, as the consumptionist believes, but because they made possible the *accumulation* of capital goods. The consumptionist does not realize that capital goods can be increased in supply only by means of an increase in their production, and that precisely this is what technological progress makes possible. Had the technological advances that made possible the first railroads in the 1830s not taken place, the supply of capital goods required for the expanded and improved railroad building of the 1840s would not have been obtainable; or, if obtainable, only at the price of the expansion of some other industry. Had no technological advances been made in railroading in the 1840s, the supply of capital goods in the 1850s would have been less, both for railroads and for all other industries. And so it would have been decade by decade, had the technological advances made in railroading or in any other industry not taken place.

For capital accumulation to continue for any period of time, technological progress is indispensable. Only it can make possible continued increases in production, and only continued increases in production can make possible continued capital accumulation. The consumptionist is not aware that the very thing that he considers to be the solution to his imagined problem is the source of what he imagines to be the problem. The absurd implication of his belief is that somehow, in the absence of technological progress, a supply of capital goods could have been accumulated out of the level of production of a preindustrial economy that would have been sufficient to build the railroads and steel mills of the nineteenth-century United States, but, thank heaven, the technology of railroad building and steel-mill construction came along in the nick of time to find uses for those capital goods. It is on this basis, under the name of the doctrine of "secular stagnation," that the consumptionist explains why large-scale capital accumulation did not depress the rate of profit in the nineteenth century, but allegedly did in this century.³²

Nor is the consumptionist aware that when he advances technological progress as the solution to the problem of what to do with more capital goods, he is confronting himself with the problem of what to do with the larger supply of consumers' goods, that even he admits results from technological progress. The consumptionist is faced, in addition to other quandaries, with the dilemma of explaining how it is that technological progress can raise the rate of profit by, as he puts it, "increasing the demand for capital," while at the same time, as he admits, it increases the production of consumers' goods, which, he maintains, lowers the rate of profit by causing "overpro-

duction,” falling prices, and “deflation.”

The textbook of Samuelson and Nordhaus provides a typical instance of this contradiction on the part of the consumptionists. In one place it declares:

But what happens as society invests in more and more capital goods? As a nation transfers more and more of its consumption toward capital accumulation? As production becomes more and more roundabout or indirect?

The answer is that we would expect the law of diminishing returns to set in. As we add more fishing boats and nets or power plants or steel mills or chemical factories or computers or trucks, the extra product or return on even more roundabout production begins to fall. The first few fishing boats or nets yield many fish, but too many fishing boats simply deplete the fish stock. Eventually, as capital is accumulated, the rate of return on the investments would fall from, say, 20 percent per annum to 10 percent or even to 2 percent.

Unless offset by technological change, therefore, rapid investment would produce diminishing returns, which would drive down the rate of return on investment. But then, why have rates of return on capital not fallen markedly over the course of the last 150 years, even though our capital stocks have grown manyfold? Because innovation and technological change have created profitable new opportunities as rapidly as past investment has annihilated them.³³

Yet while here they claim that technological progress raises the rate of return, elsewhere in their book, they say: “The opposite of inflation is deflation, which occurs when the general level of prices is falling. . . . Sustained deflations, where prices fall steadily over a period of several years, are associated with periods of deep depression, such as the 1930s or the 1890s.”³⁴

It is obvious that on this definition, technological progress must cause “deflation,” for clearly it operates to increase production and supply and therefore to reduce prices. Deflation, of course, entails a reduction in the rate of profit, or rate of return. Thus, Samuelson and Nordhaus are in the position of alleging that technological progress both raises and lowers the rate of return.

This unfortunate dilemma of the consumptionists is resolved by realizing that technological progress does not increase “the demand for capital” or the rate of profit. Rather, as already indicated, it increases the supply of capital goods, which reduces their prices and thus the costs of production. In increasing the productivity of labor, it also reduces costs of production. Thus the fall in prices of consumers’ goods is preceded by a fall in costs of production, which prevents it from resulting in a fall in the rate of profit.³⁵

Finally, it must be observed that the notion that technological progress raises the rate of profit is as mistaken as the notion that it causes deflation and thus reduces the rate of profit. Fundamentally, *technological progress is*

neutral with respect to the general or average rate of profit. It raises the rate of profit of those firms that introduce appropriate technological advances or are relatively early in their adoption. But at the same time, it reduces the rate of profit of those firms that fail to introduce such advances and suffer from the greater competition of the firms that have introduced them. If, for example, a pharmaceutical company could offer an affordable pill that would prevent cancer, it would make enormous profits. At the same time, however, various other firms, probably in a wide variety of different industries, would suffer an equivalent reduction in sales revenues and profits, at least in comparison with what they would otherwise have been. And then, if some other pharmaceutical company were to be able to offer a pill at a comparable price that not only prevented cancer but also heart disease, the pill that prevented only cancer would almost certainly incur losses. The belief that technological progress raises the general or average rate of profit is simply another instance of the fallacy of composition, based on the failure to consider the effects of things on all parties in the economic system.³⁶ The only way in which technological progress can contribute to raising the general or average rate of profit is under a system of commodity money, such as a gold standard. In that case, as I will show, it raises the rate of profit insofar as its by-product is a more rapid rate of increase in the quantity of money and volume of spending.³⁷

11. Increases in Production and Alleged Deflation

The preceding leads to the final point that must be considered here, which is not a manifestation of the consumptionist premise exclusively, but which is closely allied to it in that it implies that increases in production are responsible for depressions. This is the belief that increases in production cause deflation unless they are accompanied by equivalent increases in the quantity of money and volume of spending in the economic system.

As evidenced by the quotation from Samuelson and Nordhaus in the text above, the consumptionists, and many people who in other respects are not consumptionists, believe that falling prices in and of themselves, irrespective of their cause, represent deflation. Just as “inflation” is used as a synonym for rising prices, “deflation” is used as a synonym for falling prices. But deflation, of course, is also used as a synonym for depression. Thus, increases in production are regarded as inherently tending to produce depressions, unless, either by accident, or by virtue of the plan of the government, the quantity of money and volume of spending in the economic system grow as rapidly, and thus prevent prices from falling.

In this way, what comes to be feared is both the increase in the supply of goods and the lack of increase in the quantity of money. And what comes to be advocated, at least implicitly, is both the destruction of wealth and the inflation of the money supply—as the means of preventing “deflation.”

It should be obvious that anyone who holds these ideas must be fearful of allowing the quantity of money in the economic system to be governed by the quantity of gold. For he has no guarantee that under a gold standard, the quantity of money will increase as rapidly as the supply of ordinary goods.³⁸

Part B of this chapter shows why falling prices caused by increased production are of a radically different character than falling prices caused by a decrease in the quantity of money and volume of spending, and thus do not deserve to be stigmatized as “deflation.” It shows that none of the negative consequences associated with genuine deflation, such as a generally greater difficulty of repaying debt or a wiping out of general business profitability, accompany falling prices caused by increased production.

12. Consumptionism and Socialism

The consumptionist premise is influential not only in all the ways I have described, which are certainly important enough in their own right, but also in an important indirect way. By this I mean that while most people who hold the consumptionist premise are content to live with its paradoxical implications to the extent that they are aware of them, many are not. The latter accept all of the absurd implications of consumptionism as applying only to the capitalist economic system in which they live. Their view is that it is *under capitalism* that improvements in production cause impoverishment; that war, destruction, parasitism, and fraud cause prosperity; and that conflicts exist within and between nations. Such an absurd and discordant system, they believe, deserves to be overthrown, and replaced with an allegedly more rational system. To them, socialism appears, or at least did appear, as a system of reason and order, in which these paradoxes and conflicts can be harmoniously resolved.

The contribution of the collapse of socialism to the spread of irrationalism, which I have referred to in connection with the rise of such doctrines as environmentalism, can be understood in part in the light of the influence of consumptionism. To consumptionists the collapse of socialism means that reason simply does not apply to the economic organization of mankind. They had been convinced of the absurdity and evil of capitalism, but had looked to socialism as the solution. Now, after almost

three generations, they are coming to see that socialism means slavery and poverty. And thus, they conclude, the economic world is inherently and inescapably riddled with paradox and evil.

Some major loose ends remain to be tied up in connection with consumptionism. Above all, there is the bundle of fallacies known as Keynesianism, which represents a convoluted variant of consumptionism. I will deal with Keynesianism in Chapter 18. Of lesser prominence, but still quite significant, is the widespread fallacy that depressions are caused by too much wealth in the form of inventories. I will deal with this fallacy in an appendix following the end of this chapter.

PART B

SAY'S (JAMES MILL'S) LAW

1. Monetary Demand and Real Demand

While productionism shows that the need and desire for goods, and for the labor to produce them, have no limit, Say's Law shows that under the freedom of competition *the process of production itself creates purchasing power equal to what is produced*—that, in the typical formulation of Say's Law, “supply creates its own demand.”

There are two senses in which the word demand can properly be used in the context of the present discussion. One, is the mere expenditure of money. We may call this “monetary demand.” The other, is “real demand”—that is, the quantity of goods and services that the monetary demand, whatever it is, is capable of actually buying. Real demand is the monetary demand adjusted for the wage and price level. It should be observed that, depending on wages and prices, a smaller monetary demand can represent a larger real demand than does a larger monetary demand. For example, a monetary demand of 100 at one time can buy more than a monetary demand of 200 at another time, if, when the monetary demand is 200, prices are more than double what they are when the monetary demand is 100.

Real demand can be thought of also as the classical economists frequently described demand, namely, as *the will combined with the power of purchasing*. We have seen that the will to purchase can be taken for granted. All that is required to enlarge demand is the power of purchasing. And all that is required to enlarge the power of purchasing, as we shall see, is an increase in production. In the words of Ricardo, the desire to consume “is implanted in every man's breast; nothing is required but

the means, and nothing can afford the means but an increase in production.”³⁹

Increases in production and supply create purchasing power and real demand. They do so by virtue of reducing prices. This enables any given monetary demand to buy correspondingly more—to buy all that is produced and offered for sale.⁴⁰

Indeed, increases in production and supply are, as the classical economists held, the *only* thing that can increase real demand. In the words of James Mill, “The production of commodities creates, and is the one and universal cause which creates a market for the commodities produced.”⁴¹ This proposition becomes obvious as soon as we realize that increases in monetary demand that take place without increases in supply operate only to raise prices. The only way that increases in monetary demand can possibly represent increases in *real* demand is insofar as they are accompanied by increases in supply. Thus, increases in monetary demand alone are not sufficient to constitute increases in real demand. But increases in supply, unaccompanied by any increase in monetary demand, are fully sufficient to increase real demand.

To confirm these results, let us consider the price level formula developed in the previous chapter, namely, that the general consumer price level P is equal to D_C , the monetary demand for consumers’ goods, divided by S_C , the supply of consumers’ goods produced and sold. Thus:

$$P = \frac{D_C}{S_C} .$$

Observe. On the basis of this formula, if all that happens is that monetary demand rises, then the numerator in the formula increases while the denominator stays fixed. The effect is a corresponding rise in prices. If, for example, the monetary demand doubles, and that is all that happens, then the price level doubles. At the doubled price level, the doubled monetary demand buys no more than the original monetary demand. It is not the least bit larger as a *real demand*. The larger monetary demand is fully dissipated in the payment of higher prices and thus represents no increase in real demand whatever.

The only way that a larger monetary demand can represent a larger real demand, is, as stated, insofar as it is accompanied by an increase in supply. If, for example, when the monetary demand for consumers’ goods doubled, the supply of consumers’ goods produced and sold also doubled, *then* the doubled monetary demand would represent a doubled real demand. For the doubled supply would prevent prices from rising and thus enable the doubled monetary demand actually to purchase twice as much. An increase in supply is an absolutely indispensable condition of a larger monetary demand representing a larger real demand.

Further, the increase in supply, if any, determines to precisely what extent a larger monetary demand represents a larger real demand. If, for example, while the monetary demand doubled, supply increased only in the ratio of three to two, then real demand instead of doubling would increase only in the ratio of three to two. Our price level formula shows that in this case prices would be four-thirds as great (the doubled monetary demand divided by three-halves the supply). At four-thirds the price level, the doubled monetary demand buys only three-halves as much. All increases in monetary demand in excess of the increase in supply are dissipated in higher prices and thus do not represent increases in real demand.

Finally, an increase in supply increases real demand *without* an increase in monetary demand. The price level formula shows that an increase in supply makes the *same* monetary demand into a larger real demand—by virtue of reducing prices. For example, a doubling of production and supply in the face of an unchanged monetary demand, causes prices to halve. At the halved price level, the unchanged monetary demand buys twice as much. Thus, the increase in supply is not only necessary to the increase in real demand, it is also *sufficient* for the increase in real demand.

The principle is that under the freedom of competition, *more supply is the necessary and sufficient condition for an increase in real demand*. Its presence is what holds down prices in the face of a rising monetary demand, and reduces prices in the face of an unchanged monetary demand. In either case, it is what enables the monetary demand actually to buy more—that is, to become a larger real demand. In other words, more monetary demand without more supply just means higher prices and thus no additional real demand—it is not sufficient to create additional real demand. It takes more supply to make a larger monetary demand into a larger real demand. Thus, more supply is *necessary* for the creation of more real demand. But more monetary demand is not necessary to create a larger real demand. More supply will do it with the same monetary demand, by way of reducing prices (and, if it’s a larger supply of labor that is in question, wages). *Thus, more supply is both necessary and sufficient to the creation of more real demand*. Supply, not more money, is what counts for real demand. More money is neither sufficient nor even necessary for more real demand. Again, only more supply creates more real demand.

Figure 13–3 presents not only the productionist aggregate demand curve, which we have already seen in Figure 13–2, but also the *relationship* between aggregate real demand and aggregate supply. It shows that while the quantity of goods demanded with a fixed quantity of money and volume of spending is potentially unlimited,

the quantity of goods actually purchased—that is, the aggregate real demand that the volume of spending represents—is determined by supply. In the face of a given total expenditure of money to buy goods, under the freedom of competition it is supply that determines the price level and thus how much the given expenditure actually buys. For example, in the face of the same quantity of money and volume of spending, a doubling of production and supply from SS to $S'S'$ is what results in a halving of prices and thus in a doubling of the quantity of goods that the same quantity of money and volume of spending can buy. In the same way, a four, eight, or tenfold increase in production and supply in the face of a given quantity of money and volume of spending is what would result in prices falling to a fourth, eighth, or tenth of their initial level and thus in corresponding increases in the quantity of goods that the same quantity of money and volume of spending could buy. (This is shown by the various supply lines $S''S''$, $S'''S'''$, and $S''''S''''$.) Thus, under the freedom of competition and the ability of prices to fall, the larger is the supply, the larger is the quantity of goods demanded for any given total expenditure of money. In this way, more supply creates more purchasing power, more real demand—that is, more demand in the sense of the willingness combined with the ability to purchase goods.

There is no inherent limit to aggregate real demand. It depends only on the willingness and ability of people to produce. If they are willing and able to produce more, and free to compete, then, given the quantity of money

and the monetary demand—that is, the volume of spending—the price level will drop correspondingly and the real demand will be increased correspondingly. In this sense, the formulation of Say's Law that "supply creates its own demand" is absolutely correct.

Of course, as I previously pointed out, more production and supply do not have to operate in the context of a fixed quantity of money and volume of spending, that is, in the context of an invariable money. Indeed, under a commodity money, any substantial increase in production and supply in the economy as a whole will almost certainly include an increase in the production and supply of the monetary commodity. It will thus almost certainly be accompanied by an increase in the volume of spending in the economic system, that is, by an increase in monetary demand as well as in real demand. In other words, as supply in Figure 13-3 moves out to the right, it is reasonable to expect that over time the aggregate monetary demand curve DD would also shift upward and to the right. Thus, we might associate with the various higher supply lines respectively higher monetary demand curves. However, while this almost certainly would happen, it is not essential that it happen. For, as we have seen, the increase in production and supply is sufficient for the increase in aggregate real demand.

2. The Referents of Say's Law and Its Confirmation by Cases Apparently Contradicting It

The major misunderstandings of Say's Law arise be-

cause of a failure to keep in mind that it refers both to real demand and to aggregate demand—that is, to real demand in the economy as a whole, not to the expenditure of money to buy goods and certainly not to the expenditure of money to buy the goods of any particular industry. When these referents are forgotten, it is easy to think that Say's Law is contradicted by everyday experience. Because then one interprets Say's Law as claiming that any time anyone has an additional supply of something, he will automatically be confronted with an additional expenditure of money by his customers to buy it. One then holds this interpretation up to the light of experience and finds repeated examples in which the ruin of producers can clearly be traced to an increase in the supply of the goods they bring to the market. And one concludes on this basis that Say's Law is not only false but absurd.

In order to overcome such misunderstandings, let us consider a typical case that on the surface flatly appears to contradict Say's Law, at least when it is misinterpreted in this way. I will show how such cases not only do not contradict Say's Law, but actually confirm it.

Thus, let us consider a kind of good with which people in every industrial country are already very well supplied and want little or no more of. Potatoes are a good example. Let us imagine that because of improved methods of production, the average potato grower is able to double his output, and thus that twice the supply of potatoes is brought to the market.

Just for the moment, let us put aside the use of money, and, adopting a procedure often used by the classical economists, imagine that our potato growers live in a barter economy. Thus, when they bring their potatoes to the market, they do not exchange them for money, but directly for the various other goods they require.

Even in a barter economy, our potato growers will fare very badly. A doubling of the supply of potatoes will lead to a very sharp drop in the amounts of other goods that a bushel of potatoes can be exchanged for. If a bushel of potatoes exchanges for any amount of goods less than half of what it used to exchange for, the potato growers as a group will actually be worse off than they were before they increased their production. Because in such a case the total quantity of goods they receive in exchange for their doubled supply of potatoes will be less than it was before. In other words, the doubled supply of potatoes will result in a reduction in the real demand for potatoes in such a case.

For ease of arithmetic, let us assume that the doubled supply of potatoes results in a fall of the price of potatoes expressed in terms of other goods—that is, the barter ratios of other goods to potatoes—to one-third of what it was initially. Of course, nothing essential would be changed

if we assumed a price of a fourth or a fifth, or any other price less than one-half of the initial price. The essential thing is that we have a case in which an increase in supply makes the producers of the commodity concerned collectively worse off than they were before the increase in their supply. At one-third the price per bushel, a doubled supply of potatoes brings in only two-thirds as much in terms of other goods as did the smaller, initial supply.⁴²

Thus, here we have a case which as much as any provides a seeming refutation of Say's Law. As part of it, we can imagine the complaints of the potato growers to the effect that here is their larger supply but where is the larger demand that Say's Law claims the larger supply must bring?

Well, let us find the larger demand, because it really does exist. Only it is not a larger demand for potatoes. We can find it by starting with the reduction in demand for potatoes. The producers of goods other than potatoes—goods such as shoes, shirts, houses, hardware, and whatever—turn over to the potato growers only two-thirds the shoes, shirts, etc., that they used to turn over to them. (That is, they pay one-third the price of potatoes times twice the quantity of potatoes.)

But now, we must ask, what do the producers of goods other than potatoes do with the portion of their goods that they no longer exchange for potatoes? The answer is, *they exchange them among themselves*. The producers of shoes are able to devote one-third of the shoes they previously exchanged for potatoes, to the purchase of shirts, houses, hardware, and so on. Likewise, the producers of shirts are able to devote one-third of the shirts they previously exchanged for potatoes, to the purchase of shoes, houses, hardware, and so on. And it is the same for all other producers of goods other than potatoes.

In other words, while the "other-goods" demand for potatoes does fall (that is, the demand for potatoes in terms of goods other than potatoes), the "other-goods" demand *for other goods* equivalently rises. There is less demand for potatoes in terms of other goods but equivalently more demand for other goods in terms of other goods. When both changes in demand are added together, we see that there is no reduction in aggregate demand in the economic system, despite the reduction in the demand for potatoes.

Say's Law, of course, promises an *increase* in aggregate demand, not an unchanged aggregate demand. Where is the increase?

The increase in aggregate demand is constituted *precisely by the increase in the supply of potatoes*. In a barter economy, potatoes are, in effect, the currency used by potato growers to purchase other goods. A doubling of the supply of potatoes brought to market constitutes a doubling of the demand for other goods in terms of

Table 13–1
How an Increase in Aggregate Supply Creates a
Precisely Equal Increase in Aggregate Real Demand

1. The “other-goods” demand for potatoes is down by one-third.
2. The “other-goods” demand for other goods is up by an equivalent amount, as the customers of the potato growers use their savings from the purchase of potatoes in exchange with one another.
3. The potato demand for other goods is increased by an amount precisely equal to the increase in supply of potatoes brought to the market.

potatoes. And the producers of goods other than potatoes experience this doubled potato demand in the form of doubled potato receipts.

Thus, if we add together *all* the changes in demand accompanying an increase in supply, we find that there is indeed an increase in demand precisely equal to the increase in supply—even though it may very well be the case that there is a decrease in the demand for the particular good whose supply has increased. There is an increase in *aggregate*, economy-wide demand precisely equal to the increase in supply. These facts are shown in Table 13–1, which summarizes our example of the potato growers.

It is obvious from the table that aggregate demand increases precisely to the same extent as the increase in the supply of potatoes. For the first two items—the fall in the other-goods demand for potatoes and the equivalent rise in the other-goods demand for other goods—precisely offset one another. This leaves item three, the increase in the potato demand for other goods, as representing a net increase in aggregate demand to the same extent. Of course, the increase in the potato demand for other goods is nothing but the increase in the supply of potatoes that is brought to market. Thus, the increase in aggregate real demand in this case is precisely equal to the increase in the supply of potatoes.

Obviously the same conclusion applies to any other case that might be imagined. In a barter economy, when the supply of a given good increases, it does not matter if, as a result, the quantity of other goods offered in exchange for it decreases. Real demand in the economy as a whole still increases precisely to the same extent as the increase in the supply of this good. For the decline in the other-goods demand for it is offset by an equivalent rise in the other-goods demand for other goods, while the increase in its supply that is brought to market constitutes a further increase in the demand for other goods. Thus, when all three elements of the change in aggregate demand are added up, the result is necessarily equal to

the increase in the supply of the given good that is brought to market.⁴³

It should be clear, moreover, that even though the producers of a particular good may suffer as the result of the supply of their good being increased, the total gains in wealth in the economic system outweigh the losses precisely to the extent of the greater production of wealth. For example, while the potato growers are worse off, the producers of goods other than potatoes are better off in doubled measure. They receive not only the goods no longer received by the potato growers, but the additional supply of potatoes as well. The increase in the supply of potatoes represents the amount by which their gain exceeds the potato growers' loss.

If we return now to the conditions of a monetary economy, we will soon see how the potato growers are able to deal with their situation and to share in the benefits of the higher productivity of labor in potato growing.

We can assume that in a monetary economy, the doubled supply of potatoes results in the money price of potatoes falling to one-third of its initial level. The effect of this, of course, is that the average potato grower takes in only two-thirds as much money as before. Just as in the case of barter, he is clearly worse off than he was before the increase in potato production.

But now we must ask what people do with the money they no longer spend for potatoes. The answer, of course, is that they spend it for other things—shoes, shirts, etc. The producers of these other goods thus enjoy larger money revenues and incomes than before.

There is no increase in aggregate monetary demand in this case; just a decrease in the monetary demand for potatoes matched by an equivalent increase in the monetary demand for goods other than potatoes. But there is nevertheless an increase in aggregate *real* demand. And, again, it is precisely equal to the increase in the supply of potatoes.

For the same aggregate monetary demand now buys

all that it used to buy, *plus* the additional supply of potatoes. It is a larger aggregate real demand to precisely the same extent that the larger supply of potatoes represents a greater aggregate supply. If, for example, (allowing for the relatively small size of the potato industry in the economic system as a whole) the doubled supply of potatoes represents a 1 percent increase in aggregate supply, then the increase in aggregate real demand is also 1 percent, because the monetary demand buys 1 percent more goods in all than it did before.

Thus, Say's Law does not claim in any sense that an increase in the supply of a good means that its producers can be assured of a greater demand for *that* good and thus of greater immediate prosperity for themselves. It claims that an increase in supply is the source—the only source—of an increase in aggregate, real demand, that is (it cannot be repeated too often or stressed too strongly), of *real demand in the economic system as a whole*.

3. Partial, Relative Overproduction

It is necessary to show how the potato growers, too, ultimately come out ahead as the result of the increase in the ability to produce. In the course of this discussion, I will also show why the only kind of overproduction that can exist is a *partial, relative overproduction*—that is, overproduction in some industries counterbalanced by precisely equivalent underproduction in other industries—never a general, absolute overproduction in which the economic system as a whole overproduces.

Before economic theory can be brought to the rescue of the potato growers, it may be necessary to point out once more that this sort of case has been chosen deliberately, in order to present the opposition to Say's Law in the strongest possible light. For it is certainly not true as a general proposition, and I had no intention of implying that it is, that in every instance in which an industry succeeds in increasing its production, its producers suffer. In many cases, the producers in such an industry gain from the very outset, and gain more at first than they do later on from the improved ability to produce. If, for example, we had been dealing with a kind of good whose price would fall less than in proportion to the increase in its supply, then its producers would have been immediately better off as the result of increasing their production. But in that case, producers in other industries would have been placed in a temporarily worsened position. For example, early in this century, when the automobile was still a luxury good that only very few could afford, every improvement in the productivity of labor in producing automobiles so expanded the market for automobiles that the sales revenues and income of the automobile industry steadily grew as it increased its production

and reduced its prices. But in this case, there were short-run losses suffered by blacksmiths and horsebreeders and the like.

I would also like to point out that the fact that an industry as a whole may lose when its output is increased does not necessarily mean that everyone in that industry loses. For example, even in our case of the potato growers, if the doubling of production were the result, say, of one-fifth of the potato growers finding a way to increase their production by a factor of six, while the other four-fifths of the potato growers went on producing an unchanged amount of potatoes, this innovative one-fifth of the industry would earn doubled revenues at the one-third price, while the industry as a whole earned diminished revenues. Of course, in this event, the reduction in revenues would be all the more severe for the four-fifths of the industry that did not improve its ability to produce.⁴⁴

But let us focus on the case as initially laid out, in which all the potato growers become twice as efficient and all lose as the result of it. This is the case that most strongly seems to contradict Say's Law.

Let us begin with the respective situations of the potato growers and producers in the rest of the economic system following the doubling of the supply of potatoes. The revenues and incomes of the potato growers are badly depressed—they are only two-thirds of what they originally were. At the same time, however, the revenues and incomes of producers in the rest of the economy are somewhat elevated, thanks to the spending of funds no longer spent in buying potatoes. (Since the funds no longer spent to buy potatoes are now spread over the whole rest of the economic system, which, of course, is vastly larger than the potato industry, the percentage increase in revenue and income outside the potato industry is far less than the percentage decrease in revenue and income in the potato industry.)

The effect of the resulting sharp disparity in income between potato growers and people elsewhere in the economic system will be that some of the potato growers, observing the higher incomes to be made elsewhere, will give up potato growing and move into other lines. As they do so, the supply of potatoes is reduced—it falls to something less than double. It is still larger than it was initially, but it is less than twice as large as it was initially. At the same time, of course, the supply of goods other than potatoes is increased as former potato growers now add their efforts to the production of other goods.

The consequence of these developments is that the price of potatoes rises above one-third of its initial price, while the prices of other goods fall somewhat. As a further consequence, the incomes of the remaining potato growers begin to recover, while the incomes of

producers in the rest of the economic system begin to recede from their elevated levels.

Because the average remaining potato grower is able to grow two bushels with the same ease that he was originally able to grow only one, he will be just as well off in his capacity as an income earner as he originally was, when the price of potatoes rises to *one-half* of its initial height. Producing and selling twice the bushels at half the price will give him the same revenue and income that he had initially, when he had only his original number of bushels to sell.

Let us assume that the rise in the price of potatoes from one-third of its initial level to one-half of its initial level is accomplished when potato production is cut back from double its original amount to three-halves of its initial amount. (Obviously, we could assume any figure for potato production that was less than double and more than the initial amount. There is *some* intermediate amount of potato production that gets the price up to one-half and thus restores the incomes of the remaining potato growers. Three-halves is simply a convenient number to work with as representing this amount.)

Given the assumption that each potato grower produces double, a drop in potato production from double to three-halves is achieved when one-fourth of the initial number of potato growers leave the industry. The three-fourths of the initial number who remain, each producing double, then account for the three-halves level of potato output.

When this situation is achieved, the remaining potato growers derive the same benefit from the increase in the

productivity of labor in potato growing as producers in the rest of the economic system. And so do the former potato growers, for, by this time, they should have been able to acquire levels of experience and skill in other lines of work sufficient to enable them to earn incomes equal to those they initially earned in potato growing.

In this situation, the average member of each group—the remaining potato growers, the former potato growers, and the group composed of everyone else in the economic system, who has no present or past employment in potato growing—earns the same amount of money revenue and income as he originally earned, and, at the same time, benefits from the lower price of potatoes. Everyone gains from the fact that he now receives three-halves the potatoes for three-fourths the expenditure of money, and thus has one-fourth the money he previously expended on potatoes left over to purchase additional quantities of other goods—goods whose physical production, it must be stressed, is now possible because of the availability of one-fourth of the initial number of potato growers to produce them.

These results are presented in Table 13–2, which is titled “Say’s Law and the Process of Economic Adjustment.” The table assumes that total revenue and income in the economic system as a whole are constant at 500 monetary units, and that initially the potato growers collectively earn a revenue and income of 5 monetary units. (Each such monetary unit could be taken as representing a billion dollars some years back, or ten billion dollars today. It makes no difference which, just so long as the size is held fixed at some definite amount and is

Table 13–2
Say's Law and the Process of Economic Adjustment

	Revenue and Income of Potato Growers	+	Revenue and Income of Rest of Economy	=	Revenue and Income of Economy as a Whole
I. Initial Equilibrium (Price = 1)	5	+	495	=	500
II. Doubling of Potatoes (Price = 1/3)	3.33	+	496.67	=	500
III. New Equilibrium (Quantity = 3/2; Price = 1/2)	3.75	+	496.25	=	500

large enough so that the example can be understood as referring to the economic system as a whole. Of course, for the sake of simplicity, the example greatly overstates the relative size of the potato industry, which is certainly much less than 1 percent of the economic system.)

Condition I in the table exists before the increase in the supply of potatoes. Condition II exists immediately following the increase in the supply of potatoes. In Condition II, the initial number of growers are each producing on average double the supply, and the price of potatoes is $\frac{1}{3}$. Double the supply times $\frac{1}{3}$ the price accounts for the decline in total revenue and income in potato growing to 3.33 from 5—a drop of $\frac{1}{3}$. Revenue and income in the rest of the economic system are up equivalently, from 495 to 496.67. Revenue and income in the economy as a whole remain unchanged.

Condition III comes about after enough potato growers have left the industry to bring the price of potatoes up from $\frac{1}{3}$ of its initial level to $\frac{1}{2}$ of its initial level. At this point, because the average potato grower is producing double with the same effort that he previously produced his initial quantity, he earns the same revenue and income and is monetarily just as well-off as before the increase in the supply of potatoes.

Condition III further implies that we end up with $\frac{3}{4}$ the initial number of potato growers remaining in the industry, inasmuch as $\frac{3}{4}$ the growers times twice the output per grower equals $\frac{3}{2}$ the output, which is the amount assumed to be required to bring the price of potatoes up from $\frac{1}{3}$ to $\frac{1}{2}$ of its initial level and so restore the income of the average remaining grower. Three-fourths the initial number of growers, each on average earning the same money revenue and income as he did initially, is what explains why the total revenue and income of the potato industry is now 3.75, that is, is $\frac{3}{4}$ of 5.

The $\frac{1}{4}$ of the initial growers who leave the industry increase the supply of goods other than potatoes. A further consequence of their change in occupation is that while revenue and income in the potato industry are partially restored in rising to 3.75 from 3.33, the increase in revenue and income in the rest of the economic system is equivalently diminished. Revenue and income in the rest of the economic system come to rest at 496.25, down from the 496.67 of Condition II.

As we have seen, the net upshot of all of this is that the average potato grower, former potato grower, and nonpotato grower from the beginning, now receives $\frac{3}{2}$ the potatoes at $\frac{1}{2}$ the price, for $\frac{3}{4}$ the expenditure of money. And the average person in all groups now has $\frac{1}{4}$ the funds he previously expended for potatoes, to purchase other things, which other things can physically be produced with the $\frac{1}{4}$ of the labor released from potato growing.

Now let us take this final state of affairs, in which

potato production has been cut back to three-halves of its initial level, and the production of other goods correspondingly expanded, and use it as the *standard* for appraising the earlier situation, in which potato production had been doubled while the production of all other goods remained the same. In other words, we use Condition III as the standard for describing Condition II. From the perspective of this standard, it is clear that a *doubling* of the production of potatoes constituted an *overproduction of potatoes*. By the same standard, however, it is equally clear that going on with an unchanged production of other goods represented an *underproduction of goods other than potatoes*.

An appropriate description of things would be to say that more production in the economic system is always desirable and thus that a doubling of the productivity of labor in potato growing is desirable. However, it is a poor use of such an improvement in productivity if it takes the form merely of doubling the production of potatoes, in view of the fact that labor can be withdrawn from potato growing to increase the production of other things. Such a large increase in the supply of potatoes is much less needed than increases in the supply of other things. If the initial effect of the improvement in productivity is a doubling of the supply of potatoes, a mistake is being made. Losses and lower wages for potato growers, and higher profits and wages for producers of other things, will rectify this mistake and ensure that the effect of the higher productivity of labor in potato growing is an adequate increase in the production of other goods. Until this mistake is rectified, there is an overproduction of potatoes and a corresponding underproduction of other goods.

Thus, a doubling of the supply of potatoes represented a *partial* overproduction: it was an overproduction in one part of the economic system, while some or all parts of the rest of the economic system were correspondingly underproducing. The doubling of potatoes represented a *relative* overproduction, in that it made potato production too large in relation to production in the rest of the economic system.

In the case of a good like potatoes, it is possible that there is an absolute limit to the need, just as there appears definitely to be an absolute limit to the need for table salt. However, even if the production of potatoes, or any other good, surpassed its particular absolute limit of need, its overproduction would still be relative in the sense that the particular industry had expanded at the expense of the more necessary expansion of other industries. Its problems would be solved by the movement of capital and labor to other industries, to bring about their expansion. (In this connection, it should always be kept in mind that there is a need for improvements in the productivity

of labor even in the production of goods with which we may actually be sated, such as table salt, because then those particular goods can be produced with less labor and the labor released can be used to expand production elsewhere.)

In the overwhelming majority of cases, and possibly even in the case of potatoes as well, however, production never comes close to absolutely sating the need for the good. In all cases of this kind, the expression "relative overproduction" takes on a further meaning. For the relative overproduction of such a good could be eliminated *without any reduction whatever in the absolute amount of its production*. It could be eliminated *if the production of other goods could be sufficiently increased*.

For example, when such things as automobiles or houses are said to be overproduced, the problem is never that the need of the buyers for that kind of product is sated. The problem is that even though the buyers would still like more of this kind of good, they would like more of other goods first. If they could have sufficiently larger quantities of other goods as well, then they would like larger quantities of this good, too.

For example, almost everybody would like, if not a second automobile, then at least the equivalent of a second automobile in the form of a higher quality automobile, and, indeed, the higher-quality equivalent of a third, fourth, and fifth automobile—and, indeed, probably several such automobiles. People would gladly buy more and better automobiles if their purchasing power increased sufficiently. With doubled real incomes they would probably easily absorb a doubled production of automobiles.

Our discussion of Say's Law implies that the only thing that can give people doubled real incomes is a doubling of production. If production doubles while money incomes remain the same, prices fall in half, and the same money incomes are able to buy double. If people's money incomes double, the only thing that can keep prices the same and thus enable their doubled money incomes to buy double is a doubling of production. Thus, a *general* doubling of the ability to produce would create doubled real incomes and thus, in all probability, a demand for a doubling of automobile production.

But, now, suppose that the *only* improvement in production is a doubled ability to produce automobiles. A doubled ability to produce automobiles does not represent a doubling of real income, but an increase in real income of perhaps only 10 or 15 percent, depending on the portion of their incomes that people presently spend on automobiles. If, for example, people are presently spending 10 percent of their incomes on automobiles, and now a way is found to double automobile production, this would constitute only a 10 percent increase in their

real incomes. For the increase that is constituted by a doubling of something that represents 10 percent of people's real incomes can itself represent no more than a 10 percent increase in their real incomes.

In this context, the automobile industry would fare very badly if it in fact doubled its production. Even though people would like a doubled production of automobiles, they can hardly be expected to devote *100 percent* of their additional real incomes to the purchase of automobiles. Yet that is what would be required in this case for the auto industry alone to expand production and for the whole of the increase in production to be desired in the form of additional automobiles.

With the 10 percent higher real incomes generated by the improvement in automobile production people would probably want some increase in automobile production, more or less on the order of 10 percent, but they would almost certainly want to devote the great bulk of their additional purchasing power to the purchase of goods other than automobiles. They would want more and better housing, more and better clothing, to eat out more often, to take more and better vacations, and so on. Before they can reasonably double their consumption of automobiles, they must be able to increase their consumption of all kinds of other goods commensurately. To obtain the purchasing power necessary to do that, there must be improvements in production not only in the automobile industry, but in many other branches of industry as well.

Then, in the same way that people want to spend most of the money they save in the price of an automobile on goods other than automobiles, they will also want to spend some of the money they save in the purchase of housing, food, clothing, entertainment, etc., on automobiles. In this way, the auto industry can find an additional demand equal to a doubled supply of automobiles. For just as its improved ability to produce creates a demand for the products of other industries, so their improved ability to produce creates an additional demand for its product.

If improvements occur on a wide-ranging enough basis, then people will want substantially more of practically everything, or at least improved versions of practically everything. The appearance of a problem of overproduction arises only when and insofar as an increase in the ability to produce is overly concentrated in a particular industry or industries. In that case, an industry's problem is that its improvement creates a limited amount of additional real income most of which people want to devote to other uses, besides the purchase of its additional output. What this industry needs is more improvements in production elsewhere, so that the growth in real income will be great enough to make

possible the purchase of its additional output. If that does not happen, then what is necessary is the transfer of capital and labor out of this industry and into other industries so that a properly balanced, properly proportioned increase in production can take place throughout the economic system.

People's behavior here is guided by the law of diminishing marginal utility. They want to use their additional real income in a way that keeps marginal utility in balance in all the various lines of consumption.⁴⁵ Insofar as labor and capital can be directly or indirectly transferred from a given industry to other industries, with the result that an improvement in the productivity of labor in that industry can be made to show up as an increase in the output of other industries, failing to readjust the pattern of production to conform to the pattern of relative marginal utilities would constitute a disproportionate and wasteful use of the additional productive ability. It would represent concentrating what in fact is an improvement in the ability to produce in general within the narrow confines of the particular industry in which the improvement originates. So long as such a condition exists, there is a state of partial, relative overproduction, counterbalanced by a state of partial, relative underproduction elsewhere.

As a final, extreme confirmation of the fact that there cannot be a general, absolute overproduction, but only partial, relative overproduction, let us imagine a sudden universal doubling of the ability to produce. Everywhere, in each and every industry, the same labor is suddenly enabled to produce double. If each and every industry in these circumstances in fact began to produce double, it would be found that many industries were overproducing, but that to precisely the same extent many other industries were underproducing. If we had a doubled ability to produce and thus a doubled level of real income, we would not want double of each and every good. In the case of some goods, we would want only the same quantities, or only moderately larger quantities—certainly, much less than double the quantity. In the case of some things, we might actually want smaller quantities, as we gave up the consumption of inexpensive cheap goods in favor of more expensive, higher-quality goods. But precisely as this last statement suggests, in the case of more expensive, higher-quality goods and in the case of virtually all goods previously considered to be luxuries, we would want more than double the quantity.

Thus, while we would want probably just the same quantity of table salt and matches, and possibly smaller quantities of things like chopped meat and cheap cars, we would want correspondingly more than double of such things as sirloin steak and restaurant meals, higher-quality automobiles, better homes, swimming pools, ten-

nis courts, yachts, and so on. If the doubled ability to produce initially took the form of a doubling of everything, then the first kinds of goods would be overproduced, but the rest would be correspondingly underproduced. And what we would want is a shift of labor and capital from the overproducing industries to the industries that were underproducing. Once that occurred, we would obtain the full benefit of our doubled ability to produce, for then it would be properly proportioned to our wants. Until then, much of the improvement in the ability to produce would be wasted in producing too many more of some goods while the production of other goods was not increased sufficiently. The only overproduction would be an overproduction on the part of some industries, that was fully matched by an equivalent underproduction on the part of other industries. The overall doubling of production as such would certainly not constitute an overproduction.

Say's Law and Competition

Our discussion of Say's Law—in particular, the example of the potato growers—confirms an important point established in Chapter 9 in connection with economic competition, where it was argued that there are no genuine long-run losers under the freedom of competition. The example of the potato growers confirms this point, in that it shows how the potato growers end up benefitting even from an improvement in production whose initial effect is to depress their standard of living and take away their jobs. For once the necessary number of potato growers leave the industry and relocate elsewhere, the effect on them is that, along with everyone else, they simply get their potatoes cheaper and have the income left over to buy more of other goods, which physically can be produced because the labor required for their production is no longer tied up in potato growing.

I would like to make a modification in the potato growers example in order to make it illustrate the way in which I think competition normally operates within an industry. In my original example, of course, I assumed simply that every potato grower doubled his production and that, as a consequence, all suffered. This represented a case of competition in which all the competitors are perfectly equal and, in the circumstances of an inelastic demand for the product—that is, a situation in which the price falls more than in proportion to the increase in supply—all temporarily suffer as the result of expanding their production. It is important to realize that in most cases, the competitors are *not* all equal. At first, only a small number are able to increase their production. Only gradually does the increased ability to produce spread throughout the entire industry. The effect of this is to

enable those who introduce the improvement to gain from doing so, and to force a gradual withdrawal from the industry of those who do not introduce the improvement.

For example, let us imagine that initially only 10 percent of the potato growers are able to double their production. This represents an increase in the total supply of potatoes of only 10 percent. Given the nature of the demand for potatoes, the price will fall more than in proportion to the 10 percent increase in supply. Let us assume that it falls by 20 percent. In that case, the 10 percent of the growers who have doubled their output will greatly prosper. They will sell a doubled quantity at 80 percent of the initial price, and will thus earn 1.6 times their initial revenue and income. The entire burden of the fall in revenue and income that is experienced by the industry as a whole in selling 1.1 times the quantity at 80 percent of the initial price is experienced by the part of the industry that has not increased its production. That part of the industry simply sells its initial quantity at 80 percent of the initial price.

A withdrawal of capital and labor from potato growing will now take place on the part of producers who have not improved their productivity. And as more and more of the remaining growers adopt the more productive method, more and more of those who have not adopted it will withdraw from the industry. It is entirely possible that in this way, almost every producer who adopts the improved method will experience an increase in his individual revenue and income compared to what it was initially, while the industry as a whole continues to suffer a drop in revenue and income, with the entire drop being experienced by the producers who do not adopt the improvement. It is entirely possible that this could go on until the seventy-fifth percentile of growers doubles its output, just as the last of those who have not doubled their output leave the industry. In that case, even the last of those who adopt the improvement will experience a great gain as compared with not adopting it, and will never be worse off in their ability to earn revenue and income with the improvement than they were without it.

I think that this is the usual way in which competition operates. It rewards those who adopt improvements and puts the entire burden of an inelastic demand on those who do not adopt the improvements. The progressive adoption of the improvement finally eliminates the financial gains to be had by adopting it, except in comparison with not adopting it. Meanwhile the relocation of producers who did not adopt it into other lines enables them to restore their incomes. And, as previously explained, everyone ends up benefitting in his capacity as a consumer from the lower price of the product and the ability to obtain more goods for his money.

4. Say's Law and the Average Rate of Profit

Our discussion of Say's Law and the impossibility of a general overproduction can be reinforced by introducing alongside the price-level formula presented earlier, a second simple arithmetical formula—this time for the determination of the average level of money wage rates. Putting this new formula alongside our previous formula for the general consumer price level will enable us to see how increases in production can depress the profits of particular industries, but never the rate of profit in the economic system as a whole. The conjunction of these two formulas will also enable us later on to understand many other important economic phenomena, such as the cause and cure of mass unemployment and the determination of real wages.⁴⁶

The formula for wages is simply this: the average money wage rate earned by those who are employed is equal to the aggregate demand for labor divided by the aggregate supply of labor. The aggregate demand for labor is to be understood as manifested in a definite total expenditure of money to employ labor in the economic system, that is, in total payrolls of a definite size, such as \$1 trillion per year. The aggregate supply of labor is to be understood as manifested in a definite total quantity of labor sold, that is, in a definite number of units of labor employed, such as 100 million workers. Thus, for example, with an aggregate demand for labor of \$1 trillion per year and an aggregate supply of labor of 100 million workers, the average annual wage rate per worker that results is \$10,000. (Typically the period of time in view is a year, and the number of units of labor employed is in terms of number of employees. Thus, the average money wage rate earned is typically described in terms of annual earnings per worker. However, different periods of time than a year could be selected, and the number of units of labor supplied could also be stated in terms of the number of hours or days of labor rather than the number of employees.) Algebraically, the formula is

$$W = \frac{D_L}{S_L}$$

where W is the average money wage rate per unit of labor employed, D_L is the aggregate demand for labor, as manifested in a definite total expenditure of money to employ labor in the economic system, that is, in total payrolls of a given size, and S_L is the aggregate supply of labor, as manifested in a definite total quantity of labor employed.

Now, under a simplified view of things, total wages paid in the economic system can be taken as total costs of production, while the total spending to buy consumers' goods can be taken as total sales revenues. The simplified

view of things rests on the assumption that all business firms are vertically integrated over the entire length of the production process—for example, that General Motors owns its own steel mills, iron mines, facilities for producing iron mining equipment, and so on, and that all other companies are in a similar position. On this assumption, the only cost of production that firms would have is wages, for that is the only outlay firms would make to outside parties, since they themselves would supply all of the materials and equipment at all stages of the process leading to the production of their ultimate products. By the same token, the only source of sales revenues that firms would have would be the consumers of the ultimate, final products. As we shall see, making the assumption of the complete vertical integration of business yields results for the theory of profit that are universally applicable, because the omission of spending for capital goods results in an equal understatement of sales revenues and productive expenditure, thereby leaving the difference between them unchanged.⁴⁷ (Of course, a full analysis must include the demand for capital goods in order to be able to relate the rate of profit to all the major phenomena in the economic system that depend on that demand.⁴⁸)

As should be apparent, in the circumstances of full vertical integration of business enterprises, total profits in the economic system would equal the aggregate demand for consumers' goods minus the aggregate demand for labor—that is, the spending to buy consumers' goods, which would constitute the sales revenues of business firms, minus the total wages business firms paid, which would constitute their total costs of production. For example, if we imagine the aggregate demand for consumers' goods to be 500 units of money, while the aggregate demand for labor is 400 units of money, then total profits in the economic system would be 100 units of money.

The following formula shows this simple relationship:

$$\text{Aggregate Profits in the Economic System} = DC - DL.$$

Now the use of this formula enables us to understand more fully why any overproduction must be a partial, relative overproduction, accompanied by an equivalent partial, relative underproduction elsewhere. For the first thing that should be clear is that *the monetary profitability of the economic system as a whole is absolutely independent of its level of physical production!* So long as the demand for consumers' goods in the economic system is 500 and the demand for labor is 400, profits in the economic system are 100. If twice as much or ten times as much, or any multiple whatever, is produced and sold at one time than at another time, aggregate profits under these conditions are still 100, and the relationship of profits to sales, costs, and, by implication, capital, is

still the same.⁴⁹

Under these conditions, more production reduces the general consumer price level, but to precisely the same extent it causes a reduction in the level of unit costs. In effect, the larger output is divided into a given amount of consumer spending to produce lower prices, and into a given amount of total wage payments to produce lower unit costs. Total profit in the economic system is still the same because it is the difference merely between the two numerators—the demand for consumers' goods and the demand for labor—which are unchanged.

What we want to do now is to see how increases in production, while absolutely neutral with regard to profitability in the economic system as a whole, can have very major effects on the profitability of individual industries, accompanied by corresponding opposite effects on profitability in the rest of the economic system.⁵⁰

Thus, let us now break up the economy-wide, aggregate demands for consumers' goods and labor into two portions: that of any particular industry or group of industries, and that of all the rest of the economic system taken together. As before, let us suppose, for example, that there is an individual industry that initially represents 1 percent of the economic system. If we assume that the economy-wide aggregate demands for consumers' goods and labor are 500 and 400 respectively, then this particular industry can be assumed to spend a total of 4 units of money in paying wages and to take in 5 units of money in sales revenues from consumers. The rest of the economic system combined, of course, then spends 396 units of money in paying wages and takes in 495 units of money in sales revenues from consumers. All this is described in Table 13–3, in the form of a matrix, in the portion headed "Initial State of Affairs."

It is certainly possible for this one industry to suffer lower profits, or even outright losses, as the result of an expansion of its production. For confirmation of this fact, we need look no further than to the example of the potato growers, the essential features of which are reproduced in the table in the form of a second matrix, which is labeled "Case 1." The only difference between Case 1 and the potato growers example is the introduction of the assumption that the industry spends 4 units of money in paying wages. The fall in its sales revenues from 5 to 3.33 when it doubles its production is thus responsible for a fall in the industry's profits from 1 to (.67), that is, for a loss of .67. However, it should certainly come as no surprise that profits in the rest of the economic system are increased to precisely the same extent, as sales revenues there rise from 495 to 496.67 while wage payments remain at 396. (Apart from the introduction of wage payments, the situation is identical with that of Table 13–2, under roman numeral II.) Thus, there is no fall in

the economy-wide, aggregate amount of profit, nor therefore any reason for supposing a fall in the economy-wide average rate of profit.

Case 2 in the table depicts an increase in the given industry's production that is brought about not by a rise in its productivity but by the investment of additional capital that is withdrawn from other industries. Thus, as the result of the shifting of capital funds, the given industry is assumed to increase its expenditure on labor from 4 units of money to 8 units of money. In the nature of the case, however, this is at the expense of the rest of

the economic system cutting back its expenditure for labor from 396 units of money to 392 units of money. The result is that the particular industry doubles its production, while the rest of the economic system correspondingly reduces its production. Of course, unfortunately for the industry's investors, the consumers will buy the doubled output of this industry only for an expenditure of money that is less than doubled, that is, less than 10. This is implied by the fact that its selling price must fall, at least to some extent, in order to find buyers for the doubled quantity of its output. Thus, this

Table 13-3
Production and Profitability in the Individual Industry
and in the Economy as a Whole

Initial State of Affairs					
	A Given Industry	+	The Rest of the Economy	=	The Economy as a Whole
Sales	5	+	495	=	500
<u>Costs (Wages)</u>	<u>4</u>	+	<u>396</u>	=	<u>400</u>
Profit	1	+	99	=	100
CASE 1: State of Affairs Following the Expansion of the Given Industry by Means of an Increase in Its Productivity (A Potato-Industry-Type Case)					
	A Given Industry	+	The Rest of the Economy	=	The Economy as a Whole
Sales	3.33	+	496.67	=	500
<u>Costs (Wages)</u>	<u>4.00</u>	+	<u>396.00</u>	=	<u>400</u>
Profit	(.67)	+	100.67	=	100
CASE 2: State of Affairs Following the Expansion of the Given Industry at the Expense of the Rest of the Economic System					
	A Given Industry	+	The Rest of the Economy	=	The Economy as a Whole
Sales	7	+	493	=	500
<u>Costs (Wages)</u>	<u>8</u>	+	<u>392</u>	=	<u>400</u>
Profit	(1)	+	101	=	100
CASE 3: State of Affairs Following the Expansion of the Given Industry by Means of an Increase in Its Productivity (A Luxury-Industry-Type Case)					
	A Given Industry	+	The Rest of the Economy	=	The Economy as a Whole
Sales	6.67	+	493.33	=	500
<u>Costs (Wages)</u>	<u>4.00</u>	+	<u>396.00</u>	=	<u>400</u>
Profit	2.67	+	97.33	=	100

industry has doubled its total costs, but less than doubled its total revenue and total profits. Its profits, therefore, fall as a percentage of its costs and sales, and of its capital as well, which we may regard as having also doubled. Thus, for this particular industry, profitability declines as it expands its production.

Once again, however, to precisely the same extent, profitability in the rest of the economic system must rise! If, for example, this particular industry now takes in only 7 in revenue, say, which is the specific assumption made in Table 13–3, while it incurs total costs of 8, then the rest of the economic system takes in total sales revenues of 493, while incurring total costs of 392. Thus, the rest of the economic system earns 101 in profits, while this industry suffers a loss of 1. What the table shows is that to the same extent that sales revenues fail to keep pace with total costs in the given industry, they expand relative to total costs in the rest of the economic system. This is mathematically inescapable, so long as total sales revenues and total costs in the economic system as a whole remain constant. Thus, while profits in the given industry fall by 2, from +1 to -1, they rise by 2 in the rest of the economic system, namely, from 99 to 101.

Table 13–3 presents one other case, Case 3, which assumes that a given industry increases its productivity in the face of an elastic demand for its product, rather than an inelastic demand. It is described as “A Luxury-Industry-Type Case,” in contrast to Case 1, which is described as “A Potato-Industry-Type Case.” Just as in Case 1, the industry is assumed to find a way to double its output by virtue of increasing its productivity. In Case 3, however, instead of the doubled output causing the price to fall by two thirds, it is assumed that the doubled output causes the price to fall by only one third. Thus the industry’s expenditure of 4 for labor is now accompanied by sales revenues 6.67. This represents an increase in its profits from 1 to 2.67. But just as the fall in the profit of the given industry in the previous cases did not represent a fall in the economy-wide amount of profit, so now the rise in the profit of the given industry does not represent a rise in the economy-wide amount of profit. The rise in the industry’s profitability is the result of the improvement in its competitive position relative to other industries. By virtue of being able to offer its goods less expensively, it leads large numbers of buyers to shift their expenditures from other industries to it. Its additional products find such favor that the reduction in price attracts additional buyers more than in proportion. The obvious result, which the table shows, is that the increase in the given industry’s profitability is at the expense of an equivalent decrease in the profitability of the rest of the economic system.

Thus, in all cases, the change in sales revenues, costs,

and profits of the given industry, whether in the downward or upward direction, is shown to be accompanied by opposite changes in the sales revenues, costs, and profits of the rest of the economic system. This, as I say, is the inescapable implication of the aggregate demands for consumers’ goods and labor remaining the same. The table shows that while profitability in the particular industry can fall as the result of an overexpansion in its production *relative* to the rest of the economic system, profitability in the rest of the economic system correspondingly rises. It makes clear that the proposition that there can be no fall in general profitability, no matter how great the increase in production, is perfectly consistent with the fact that profitability in any given industry or group of industries can be reduced by an increase in its production. The reconciliation is that profitability in any given industry is determined by its *competitive* status, which changes in the industry’s production relative to that of other industries can profoundly influence. At the same time, however, as I have said—and it cannot be stressed too strongly—the general profitability of the economic system as a whole is independent of the level of physical production. It is independent of all competitive factors—which, in the nature of the case, are always mutually offsetting. What aggregate profit depends on, basically, is *consumption spending minus wages*; from the perspective of the economy as a whole, the level of physical production acts only on the general price level and on the buying power of wages, not on profitability.

To say the same thing in different words: the determinants of aggregate profits and the average rate of profit in the economy as a whole are different than the determinants of the amount and rate of profit of any individual industry. The determinants of the former comprise above all the difference between the demand for consumers’ goods (sales revenues) and the demand for labor (costs). Changes in the magnitude of production and in the price and wage level are simply irrelevant, so long as these two aggregate demands are the same. At the level of the economic system as a whole, the phenomenon of competition is not operative. Its effects on profits and losses are mutually offsetting. But at the level of individual companies and industries the effects of competition on the rate of profit are decisive. Insofar as increases in production place the marginal utility of an industry’s product at a competitive disadvantage with the marginal utility of the products of other industries, its profitability is reduced or even wiped out altogether. By the very same token, however, the profitability of the rest of the economic system is equivalently increased. There is no effect on the aggregate amount or average rate of profit in the economic system as a whole.

Production and the Fallacy of Composition

If we keep the preceding discussion in mind, then it is possible to grasp more fully the nature of the mistakes underlying the consumptionist belief in the possibility of a general, absolute overproduction. Apart from the underlying mistaken philosophy that man's true, legitimate needs do not differ significantly from those of an animal, is, above all, the fact that it is possible for *any* given industry, at one time or another, to be in the position of incurring losses as the result of overexpanding relative to the rest of the economic system. Absolutely any industry could find itself in the position of our given industry and incur losses as the result of expanding its production.

The actual cause of its losses, of course, would be its *relative* overproduction, and there would exist at the same time a precisely equivalent relative underproduction in the rest of the economic system. But the businessmen in the industry concerned would be correct in concluding that the cause of their particular problem of low profits or losses was that they had carried their production too far. Not being philosophically inclined or familiar with classical economics, they would be neither aware of nor concerned with the effects of their action on the profitability of other industries. In looking only at their own particular industry, they would conclude, and again and again do conclude, that losses result simply from excessive production. And then, when there is a general business depression, and practically all industries suffer losses, they, and most other observers, conclude that the explanation is that *all* of the industries are overproducing. Their fallacy is the same as that which leads many businessmen to the mistaken conclusion that need is synonymous with demand and that what is needed for more demand is more needs because an increase in the need for any particular product relative to the need for other products that are currently being purchased can increase the demand for that product.⁵¹

The fallacy, of course, is the fallacy of composition—i.e., the error of assuming that what is true of part of a system is automatically true of the system as a whole. This fallacy is what makes the overproduction doctrine seem plausible. The fallacy of composition arises again and again in economics because of a failure to think out the implications of events in particular industries for the rest of the economic system. It arises because of a failure to realize that every given industry is in a state of competition with the rest of the economic system—either having its sales revenues and profits competed away by the rest of the economic system or itself competing sales revenues and profits away from the rest of the economic system. The fallacy of composition plays a prominent role in the consumptionist belief that a general, absolute overproduction is the cause of depressions insofar as that

belief rests on an invalid generalization from the conditions of a particular industry to the economy as a whole. To repeat, any particular industry might at some time or other suffer low profits or losses as the result of a problem of partial, relative overproduction. But when it does, the rest of the economic system earns correspondingly higher profits as the result of a precisely equivalent partial, relative underproduction. It is the fallacy of composition par excellence to conclude that when all industries suffer losses, as is the case in a general business depression, it is the result of a general overproduction.

A general business depression has absolutely nothing to do with the level of production in the economic system. Less production would do nothing to alleviate depressions. It would only reduce the general standard of living. To whatever extent the profits of particular industries might be increased by reduced production in those industries, the profits of other industries would only be further reduced. And, as I say, the general standard of living would be reduced. Depressions are not the result of anything on the side of production or supply. *They are a monetary phenomenon.* That is, they originate on the side of money and spending—on the side of monetary demand, not production and supply. They are the result of a sudden contraction in aggregate spending for goods and labor, which makes the repayment of debt more difficult, reduces the general profitability of business, and precipitates mass unemployment. As the previous chapter showed, and as Chapter 19 will show more fully, this contraction, in turn, is the result of a preceding artificial monetary expansion caused by government interference in the economic system. In sum, it is the contraction in spending, brought on by a previous inflationary boom, that causes all the leading symptoms of a depression. The cause is *not* the increase in production.

5. Falling Prices Caused by Increased Production Are Not Deflation

A major implication of the fact that increases in production do not reduce the general rate of profit is the fact that *the falling prices caused by increases in production do not represent deflation.*

The fact that the falling prices resulting from increasing production are not accompanied by a decline in the general or average rate of profit represents an enormous departure from the conditions of a genuine deflation. In a genuine deflation, business profits are almost universally depressed, if not eliminated altogether. But we have seen that the aggregate profit of the economic system can be represented by the difference between the spending of consumers to buy products and the wages paid by business to produce them, and that so long as those magni-

tudes, and thus the difference between them, remain the same, the aggregate profitability of business is totally unaffected by the physical volume of goods and services produced and sold. Thus, when production increases, prices fall. That is perfectly true. But the general rate of profit does not.

By the same token, when prices fall because of an increase in production, there is nothing present that would cause any general increase in the difficulty of repaying debts, which is the most prominent symptom of a genuine deflation. A fall in prices resulting from more production in the face of constant sales revenues does not mean that there is any greater difficulty of earning any given sum of money. If, over a period of years, an increase in production, let us say a doubling, is achieved by virtue of business firms becoming more efficient, then the conditions of the case imply that the mathematically average business firm produces twice the output just as easily as it previously produced its original output. True enough, a unit of output sells for only half the price. But, by the conditions of the case, the average business firm *has twice the units to sell*. Its sales revenues in money are, therefore, just as great as they were before, and no more difficult to earn. Whatever money it is obliged to repay, does not come to it with greater difficulty than was originally the case.

It is certainly true that individual firms and whole industries could find it more difficult to repay their debts as prices fell. These would be the firms that did not improve their efficiency while their competitors did, and the industries that were relatively overexpanded. These firms and industries would suffer a decline in sales revenues and profits, and probably incur outright losses. But for every firm and industry in this position, there are other firms and industries that enjoy correspondingly increased sales revenues and profits and a correspondingly enhanced ability to repay their debts. Namely, the firms that introduce improvements ahead of their competitors, and the industries that are relatively underexpanded. There is no *overall pressure on debtors here—nothing present that operates against debtors as a class*.

Thus, it is simply incorrect to think of falling prices per se as “deflation.” The falling prices caused by more production share only one symptom of deflation—namely, the fall in prices itself. They do not share two further, essential symptoms of deflation—namely, the sudden reduction or total elimination of business profitability and the increased difficulty of repaying debts.

What accounts for the combination of these three symptoms of deflation together is not any increase in production or supply, but a *decline in monetary demand*—a contraction of spending—which occurs as the result of a drop in the quantity of money or at least a

slowing down of its rate of increase. A drop in total spending reduces prices. That is one of its effects. In addition, and totally unlike an increase in production and supply, it also reduces total business sales revenues. This reduces the availability of funds with which to repay debts. It makes it more difficult for the average seller to earn any given sum of money, because there is simply less money to go around. In addition, and again totally unlike an increase in production and supply, a drop in total spending reduces the general rate of profit, because while sales revenues fall immediately as a consequence of a decline in spending in the economic system, total costs of production in the economic system fall only with a time lag. For example, depreciation cost continues to reflect the larger volume of spending on account of plant and equipment that existed in the past.

Thus, deflation is a monetary phenomenon, not a phenomenon originating on the side of production. It should be thought of as a contraction in the volume of spending in the economic system, precipitated by a decrease in the quantity of money or slowing down of its rate of increase. For this is the underlying phenomenon that produces the *cluster* of symptoms that constitute deflation, not merely the one, isolated symptom, the fall in prices, that deflation shares with increases in production.

It is nothing less than absurd, indeed, vicious, to equate deflation with increases in production on the basis of their sharing this one, isolated symptom of falling prices while being of an absolutely opposite nature in connection with their effect both on the average rate of profit and on the general ability to repay debts. It is the wiping out of profitability and the sudden increase in the difficulty of repaying debts that is the substance of the evil produced by deflation. This has absolutely no connection with increases in production and the fall in prices brought about by increases in production. To view the fall in prices brought about by increased production as the same as deflation and depression is gratuitously to confuse the enormous economic good that is constituted by increases in production with the evil that is constituted by depressions. It is difficult to imagine a more profound or devastating error.

The Anticipation of Falling Prices

The question arises of whether the anticipation of falling prices caused by increases in production could have deflationary effects—i.e., could the prospect of steadily falling prices lead people to increase their demand for money in anticipation of being able to buy more cheaply later on? And, if so, wouldn't this be equivalent in its effects to a reduction in the quantity of money? And thus, on these grounds, shouldn't increasing production be

called deflationary after all?

The answer to these questions is no. The prospect of falling prices *caused by increases in production*, rather than by decreases in the quantity of money and volume of spending, does not operate to increase the demand for money. And thus it does not operate to reduce the velocity of circulation of money and the volume of spending in the economic system.

The first thing that must be pointed out is that even if the prospect of falling prices caused by increases in production did increase the demand for money, which it does not, the increase would be of an essentially one-time nature. Once the increase in the demand for money took place, further increases in production and the falling prices they caused would take place with no further increase in the demand for money.

For example, let us suppose that there is a given, fixed quantity of money in the economic system and that initially the aggregate demand for consumers' goods is 500 monetary units and the aggregate demand for labor is 400 monetary units, as in our previous example in connection with Say's Law and the rate of profit. We can assume that initially production and prices are both constant from year to year. And now we assume that production begins to rise and prices to fall from year to year and, for the sake of argument, in response to the fall in prices and the prospect of the fall continuing, the demand for money rises. If it occurred, the rise in the demand for money would have the effect of reducing the monetary demand for consumers' goods and labor. For the sake of illustration, let us assume that the effect would be to reduce the demand for consumers' goods and labor by 10 percent, namely, from 500 and 400 respectively to 450 and 360 respectively. From this point on, it is clear, production would increase and prices would fall with no further increase in the demand for money and no further fall in the monetary demands for consumers' goods and labor.

Under no conditions could the prospect of falling prices be assumed to cause a continuing, endless increase in the demand for money. At most the prospect of some rate of fall in prices could plausibly be argued to result in some defined, delimited rise in the demand for money, which would then result in some delimited drop in expenditures and thus be satisfied. The only reasonable basis for a further rise in the demand for money based on the anticipation of falling prices caused by increases in production would be if the rate of increase in production and fall in prices *accelerated*. In that case, it might plausibly be argued that there would be a one-time further increase in the demand for money and a one-time further fall in the aggregate demands for consumers' goods and labor.

Thus, even if the argument alleging deflationary effects were correct, which it is not, it would still be essentially false. For at most, it would apply only to a transition phase. Thereafter, once the additional demand for money was satisfied and the volume of spending in the economic system stabilized at a lower level, production could go on increasing and prices go on falling at any given rate with no further increase in the demand for money, exactly as I have described.

As I say, however, there is no basis for assuming that falling prices caused by increased production bring about a rise in the demand for money. Insofar as the increasing production and falling prices are the result of improvements in the productivity of labor, the falling prices do not lead to a postponement of consumption and thus do not increase saving at the expense of consumption. This is because they are the accompaniment of the average person having a higher real income and thus being better off in the future than in the present, which prospect gives him as much motivation to consume more as the prospective increase in the buying power of money gives him to postpone consumption and save more.⁵² Inasmuch as the two incentives are thus mutually offsetting, there is no overall tendency for consumption spending to fall, or saving to increase, as the result of falling prices caused by increases in production—not insofar as the increases in production and fall in prices are the result of a higher productivity of labor.

When increases in saving do occur, the demand for money does not increase, but, if anything, decreases. This is because, as we shall see after we have studied their determinants, the average rate of profit and interest in the economic system is always both positive and sufficiently high—in the absence of monetary contraction—to make it worthwhile to invest savings that are available for any significant period of time rather than hoard them. In such an environment, as we saw in the last chapter, the effect of an increase in saving is actually to reduce the demand for money, both because funds that are saved are normally available for spending sooner than funds that are held for consumption and because savings are the source of credit, the prospective availability of which reduces the need to hold money.⁵³

Thus, the falling prices brought about by increased production do not result in a rise in the demand for money or have deflationary effects. Indeed, it should be realized that under a system of gold or silver money, an increasing ability to produce on any kind of broad, substantial scale almost certainly means the production of a larger quantity of these metals and, insofar as it represents an increase in a country's ability to produce relative to the rest of the world, the attraction of a larger proportion of the world's supply of such precious metal money to its

shores. The larger quantity of money caused in these ways by an increased ability to produce implies a *growing volume of spending*, not a diminished volume of spending. Indeed, on a commodity money system, only an increasing ability to produce can bring about a growing quantity of money and rising volume of spending in the long run. Thus, under a commodity money system, the falling prices that are caused by increases in production actually take place in a context in which there is almost certainly an increase in the quantity of money and volume of spending.

What this means is that when prices fall because of increases in production, there is almost certainly some increase in the quantity of money and volume of spending taking place at the same time, as part of the increase in production itself, or at least on the foundation of the increase in production itself (the latter as far as matters pertain to international trade and the relative size of a country's production in the world economy, and hence its ability to garner part of the increase in the world supply of money). Thus, to whatever extent prices fall because of an increase in production, the fall is almost certainly not in full proportion to the increase in production, but only in proportion to the amount by which the increase in production exceeds the rise in monetary demand that takes place at the same time and in connection with it. For example, in conditions in which prices might fall perhaps 2 percent per year because of increasing production, the fall would almost certainly reflect a condition of the kind in which the quantity of money and volume of spending increased on the order of, say, 1 to 3 percent per year while the supply of goods increased on the order of, say, 3 to 5 percent per year.

Thus, falling prices caused by increased production are so far removed from deflation and financial contraction that they are actually part of a process in which the quantity of money and volume of spending grow from year to year. And, as we already have reason to know, this increase in the quantity of money and volume of spending both adds to the rate of profit and interest and, in increasing the sales revenues of the average seller in the economic system, correspondingly reduces the difficulty of earning the money that is required to repay debts. For example, in a context in which prices fall 2 percent per year because production increases 5 percent per year while the quantity of money and volume of spending increase 3 percent per year, the average seller in the economic system enjoys a 3 percent per year increase in his sales revenues. The position of the average seller—that is, a seller who has increased his production in accordance with the economy-wide increase of 5 percent per year—is that the supply of goods he has available to sell at the 2 percent per year lower prices is 5 percent per

year greater. Thus his sales revenues are 3 percent per year higher. In this case, the average seller would actually have considerably less difficulty in earning the money with which to repay his debts than when he borrowed the money. This is because, other things being equal, after he borrowed he would be able to earn 3 percent more money per year than the amount he earned at the time he borrowed, with no greater difficulty on his part.

Hopefully, on the basis of all of the foregoing, it is now even clearer than before that the existence of falling prices accompanied by a contraction in spending and the other symptoms of deflation and depression is not the result of increases in production. We have seen that the relationship between the prospect of falling prices and a greater demand for cash holdings pertains to falling prices caused by a decrease in the volume of spending, not to falling prices caused by increases in production. The decrease in the volume of spending in turn is the result either of a decrease in the quantity of money or a reduction in the rate of increase in the quantity of money, the latter in an environment in which the demand for money has first been artificially reduced by virtue of more rapid increases in the quantity of money.⁵⁴ In such a situation, the desire to hold cash balances increases and the velocity of circulation of money falls, in accordance with the principles explained in Chapter 12.⁵⁵

In sum, the particular nature of the cause of the fall in prices is essential for the effect on the demand for money. Only those price reductions emanating from monetary contraction cause a rise in the demand for money.

Economic Progress and the Prospective Advantage of Future Investments Over Present Investments

Similar to the question of whether the prospect of falling prices resulting from increased production causes a rise in the demand for money is a question pertaining to the effects of prospective improvements in machinery on the profitability of investing in the machinery of today. Thus, to the extent that there is economic progress, the machines of the future will be more efficient than those of the present and therefore today's machines will be at a competitive disadvantage in comparison with them. The question that arises is whether this circumstance might operate to depress current investment by creating the prospect of losses or, at any rate, lower profits than could be obtained by delaying investment, and whether it might thus operate to cause an increase in the demand for money as well as to inflict losses on the producers of plant and equipment, who would have to cut their prices in the present in order to be competitive with the plant and equipment of the future.

The answer is that if economic progress took place only once, or were just about to take place for the first

time, then it would be true simply that the machines of the present would be at a competitive disadvantage with the machines of the future, with the result that a rise in the demand for money might ensue and the new machines of the present might have to be sold at a loss if their competitive disadvantage were major. Observe, however, that the increase in the demand for money would exist only until the expected more advanced machines arrived on the market, and the loss would be borne only by the machines which did not embody the progress. The arrival of the more advanced machines would put an end to any increase in the demand for money. They would be in demand and would not sell at a loss. More importantly, it should be realized that if improvements in machinery are a repeated occurrence and are expected, there is no increase in the demand for money and no problem of the owners or producers of machinery incurring losses because of the prospective introduction of more efficient machines in the future.

This is because in such conditions, while the machines of next year may be expected to be more efficient and at a competitive advantage over the machines of this year, the machines of this year are, for their part, more efficient and at a competitive advantage over the machines of last year and previous years. Because of their greater efficiency and higher productivity, the machines of this year account for a disproportionately large share of total production, when compared to the machines of last year and previous years.

For example, if the average machine lasts twenty years, and the machines in use at any given time range in age from brand new to twenty years old, the current year's machines, being relatively more efficient and more productive, will account for more than one-twentieth of the production of the economic system and will earn more than one-twentieth of the total revenues attributable to machinery. If not for the prospective introduction of still more efficient machinery in the years to come, the machines of this year would be *extraordinarily profitable*. The fact that they, in turn, will be superseded means merely that a part of what would otherwise represent extraordinary profits must be set aside to compensate for the time when they will be of below-average efficiency. In other words, the effect of continuous economic progress is not to make the machinery of the present continuously unprofitable or less profitable, because the machinery of the future will be better, but to require a system of *more rapid depreciation in the earlier years of a machine's life*, when it possesses above-average efficiency. Its competitive advantage in the early years of its life compensates for its competitive disadvantage in the later years of its life.⁵⁶

Similar observations apply to the case of inventory

and the fear that business would always have to sell its inventories at a loss, because of continuously falling costs and prices. The fact is that to the same extent that older inventories must be sold at a loss, newer inventories can be sold at a correspondingly enhanced profit. This proposition can be demonstrated for the case of any given rate of increase in production and any given ratio of inventories to sales. If, for example, production were to double from period to period, and half of current production were always to remain in and constitute inventory, then in any given period sales would represent half of the production of the current period plus half of the production of the previous period, which was half as great. Thus, two-thirds of current revenues would be attributable to half of the production of the current period and one-third of current revenues would be attributable to half of the production of the previous period. To the same extent that the half of the production of the previous period brought in deficient revenues, the half of the production of the present period that is currently sold would bring in additional revenues. Thus, the general rate of profit would not be affected. What is present here is nothing fundamentally different from the fact that businesses are profitable despite the fact that they run clearance sales on which, considered in isolation, they incur a loss; the losses on the clearance sales are compensated for by the profits on regular operations.

I have said that if economic progress took place only once, or were just about to take place for the first time, then it would be true simply that the machines of the present would be at a competitive disadvantage with the machines of the future, with the result that a rise in the demand for money might ensue and the new machines of the present might have to be sold at a loss. This is actually an overstatement of matters, because unless such a situation were pervasive, that is, applied to the greater part of the economic system at the same time, the decline in expenditure to buy the machines even of a fairly substantial number of industries would almost certainly not represent a decline in expenditure in the economy as a whole. The funds not expended for the machines in question would be made available for other purposes and be expended elsewhere. The only way that spending in the economic system as a whole would be reduced is if economic progress throughout the economic system, or at least in the greater part of the economic system, were about to take place for the first time or, what would be very similar, were about to undergo some significant acceleration. Only in such unusual cases, would spending in the economic system as a whole temporarily fall, awaiting the appearance of the improved machines.

While such a case is unlikely in connection with

improvements in machinery, it has important application to the labor market in the context of mass unemployment, as I will show in Part C of this chapter. Specifically, in the conditions of the prospective fall in wage rates and prices, and thus in the costs of investments, that mass unemployment entails, not only does an increase in the demand for money ensue, but government intervention that prevents wage rates and prices from falling lengthens its duration and thus lengthens and deepens the depression. This is because it prevents the restoration of demand that would occur upon the costs of investments made in the present coming down to a level competitive with their prospective cost in the future.⁵⁷

Falling Prices and Accumulated Stocks

The case of goods such as housing and automobiles, that is, goods with substantial accumulated stocks and important markets for such accumulated stocks, may appear to represent a partial exception to the principle I have advanced that falling prices caused by increased production do not reduce the aggregate or average ability to repay debts because the fall in prices is accompanied by an inversely proportionate increase in the supply of goods.

In the case of goods with substantial accumulated stocks, the rate of increase in production and the rate of increase in the quantity of accumulated stock, while always ultimately tending to be equal, can be substantially different for more or less protracted periods of time, whenever the rate of increase in production changes. For example, if after being stationary for many years, the production of new houses should begin to increase at a compound-annual rate of 5 percent, the rate of increase in the accumulated stock of housing will be much less than 5 percent for many years. Indeed, if the accumulated stock of housing is initially 50 times as large as the annual production of new housing, the first 5 percent increase in the production of new housing will constitute an increase in the stock of housing of only .1 percent, that is, 5 percent divided by 50. Only after 50 years of a 5 percent compound-annual rate of increase in new housing construction, would the accumulated stock of housing also increase by 5 percent per year.⁵⁸

If, under these conditions, the price of housing fell on the order of 5 percent per year starting as soon as the annual production of housing began to increase at 5 percent per year, the result would be that for 50 years the price of housing would fall more than in proportion to the increase in the accumulated stock of housing. A further implication would be a severe decline in the aggregate monetary value of the housing stock and, of course, in the ability of the average homeowner to repay his mortgage out of the proceeds of the sale of his house.

In answer to the possibility of this kind of argument, it is necessary to point out that in cases in which the accumulated stock is so significant, the price of a good should not be expected to fall in proportion to the rate of increase in its production, so long as the rate of increase in its production is so much larger than the rate of increase in the accumulated stock of the good. A 5 percent annual increase in the production of housing should not be expected to reduce the price of housing on the order of 5 percent, so long as all that it represents is a .1 percent increase in the total accumulated stock of housing. Such a situation would imply an extremely inelastic demand for housing.⁵⁹

A more reasonable estimate for the extent of the fall in the price of housing under such conditions must allow for the fact that alongside the money expended in constituting the demand for new housing is the money expended in constituting the demand for already existing housing. Of course, even under an invariable money, the combined sum of these two demands is capable of undergoing change in the face of a change in the production and accumulated stock of housing. This is because people can shift the expenditure of funds either away from housing to other things, or to housing from other things. For the sake of ease of analysis, however, let us assume that the overall expenditure for housing, newly produced and already existing combined, remains the same. Under these circumstances, if the average homeowner were in the habit of moving every year, the annual expenditure for housing would initially be on the order of 50 times the annual expenditure for new housing, inasmuch as the total quantity of housing sold in a year would be 50 times the production of new housing. In this case, an increase in the housing stock of .1 percent would result in a decrease in the price of housing also on the order of .1 percent. In such circumstances, the fall in the price of housing would be precisely counterbalanced by the increase in the supply of housing, and the aggregate value of the housing stock would remain absolutely unchanged.

In reality, of course, the average homeowner does not move as often as every year. For the sake of argument, let us assume that he moves only once every 5 years (which is probably too conservative an assumption). In this case, if the existing housing stock is initially 50 times as large as the current year's production of housing, the overall funds expended for housing will be on the order of 10 (i.e., $50/5$) times the funds expended for new housing, which is still an enormously greater magnitude and, as I say, probably too conservative an estimate. In this case, if the aggregate demand for housing remained the same in the face of a supply of housing sold in the market that consisted of the sum of one-fifth of the existing housing stock plus production of new housing that was

5 percent larger than the previous year's production of new housing, the initial fall in the price of housing would be on the order of .5 percent. For in this case, the initial overall increase in market supply would be on the order of .5 percent, inasmuch as the 5 percent increase in the current production of housing must be divided by the previous year's market supply that was 10 times as large as the previous year's current housing production.

In this case, there is some modest tendency toward a fall in the aggregate value of the housing stock that will go on over a protracted period of time. But what is highly significant in this or any such case is that even with total demand for the item being fixed, there is a pronounced tendency for *the regular business sellers*, as opposed to those who sell their previously purchased goods (whether consumers or businesses), actually to enjoy *growing sales revenues in the period of adjustment*. This is because the increase in supply is concentrated in their hands. And thus, from year to year they claim a growing proportion of the total funds expended to buy such goods. For example, starting with an aggregate demand for housing that is 10 times the size of the demand for new housing, the proportion of that aggregate demand that is claimed by new housing will go on increasing so long as the supply of new housing goes on increasing relative to the overall housing stock and thus the market supply of housing.⁶⁰

The principle that emerges from this discussion is that as the result of increasing production, or a more rapid rate of increase in production, the proportion of any given economy-wide aggregate demand that is claimed by current production, as opposed to previously produced goods, goes on increasing until the rate of increase in the supply of previously produced goods catches up. Thus, from the perspective of *business*, the effect of increases in production and the falling prices they cause is analogous to the effect of the economy of one country growing relative to that of others. Namely, it attracts a growing proportion of the quantity of money and volume of spending of the economic system to the segment that is increasing relative to the rest of the system.

As for the value of the preexisting stock, what is present is only some measure of increase in the normal kind of loss of value that follows the purchase of goods. And this loss of value, I must point out, is mitigated, even if not entirely overcome, by the increase in the quantity of money and volume of spending that accompanies large-scale increases in production as a virtually inevitable by-product. Thus, even in the face of a growing population, there is almost certainly no reduction in the ability of the average member of the economic system to earn any given sum of money and thus to repay debts. (And, as we shall see very shortly, even if the growth in

population and the supply of labor did bring about modestly falling wage rates, the effect would be of no long-run significance.) Moreover, in the case of housing or any other expensive durable good, where the demand is entirely dependent on saving, it is likely that the achievement of economic progress or more rapid economic progress would be founded at least in part on an increase in the proportion of economy-wide aggregate demand that is devoted to the purchase of such goods. This would be the case insofar as the process of economic progress was inaugurated by a rise in the degree of saving.⁶¹

Thus, it is virtually impossible that economic progress or more rapid economic progress, would ever for very long be accompanied by any actual reduction in the aggregate nominal value of the stock of housing, automobiles, or any other such goods; rather, it would be accompanied by a continuing rise, and probably from the very beginning. It is equally impossible that it would cause the difficulty that the average member of the economic system experiences in repaying his debts to be any greater than whatever difficulty he normally experiences in repaying debts for such things as the purchase of automobiles or major appliances. For example, even if it were the case that the price of houses fell on the order of 5 percent a year, so long as the money income of the average homeowner remained the same, or fell only modestly, his difficulty in repaying mortgage debt would be no greater than is the difficulty of automobile purchasers, say, in repaying automobile installment debt, which debt is typically repaid out of income rather than the rapidly declining resale value of used cars.

In addition to all of the foregoing, it is necessary to realize that at least in the very important case of housing, the source of increases in supply is not confined to new production. This is because it is possible to varying degrees also to increase the supply represented by the preexisting stock—for example, through all manner of home improvements. To the extent that this occurs, the resale value of older units of the supply is maintained, for they themselves participate in the increase in supply. If our hypothetical 5 percent annual rate of increase in the housing supply were achieved mainly in this way, the price of a base unit of housing might fall on the order of 5 percent a year from the very beginning and there would be no necessary fall in the aggregate value of the accumulated stock of housing even under the assumption of the most rigidly fixed aggregate monetary demand for housing; at the same time, the resale value of older units of the housing stock would be maintained.

Falling Prices Resulting from a Larger Supply of Labor

I turn now to the final variant of the fallacy that falling

prices caused by increases in supply constitute deflation. This concerns the fact that a growing supply of labor tends to reduce wage rates. It might be thought that to the extent that wage earners have debts, a fall in their wage rates brought about in this way would constitute a leading symptom of deflation. This would not be so, however, for a number of reasons.

First of all, insofar as the larger supply of labor represents the employment of more married women or more offspring of the initial workers, there is no decline in the income of the average working *family*. There is just the fall in prices of goods that results from the greater production. Thus there is an increase in the real income of the average working family and, therefore, almost certainly an increase in its ability to repay any given amount of debt.⁶² Insofar as the larger supply of labor is the result of immigration, then, it is true, there is a reduction in the income of the average working family already present and a correspondingly greater difficulty for such a family in repaying debts. But, by the same token, there is an increase in the income of the immigrant families and a correspondingly reduced difficulty of repaying debts as far as they are concerned. There is no greater difficulty of repaying debts on the part of the average working family as such. Such a general greater difficulty could occur only to the extent that the aggregate demand for labor fell. As we know, the only explanation for such a fall taking place suddenly and dramatically is a decrease in the quantity of money and/or an increase in the need to hold money, which latter follows from a decrease in the quantity of money or reduction in its rate of increase.⁶³

Finally, it should be realized that if a fall in wage rates resulting from a growing supply of labor were accompanied by a greater difficulty of repaying debts, the difficulty would not be lastingly alleviated by a more rapid increase in the quantity of money that would prevent the fall in wage rates. As subsequent discussion will show, if the rate of increase in the quantity of money were stepped up to keep pace with the rate of increase in the supply of labor, the result would be a rise in the nominal rate of profit and interest by the same percentage. This means, for example, that if a 2 percent annual increase in the supply of labor were operating to reduce wage rates on the order of 2 percent a year, a 2 percent annual increase in the quantity of money and volume of spending, which would make possible a 2 percent annual increase in the demand for labor and thus prevent wage rates from falling, would ultimately add 2 percentage points to the average rate of profit and interest in the economic system. In other words, if the average rate of profit and interest would otherwise be 4 percent, now it would be 6 percent.⁶⁴ Thus, while workers would not experience

a fall in their money wages any longer, they would have to pay a correspondingly higher rate of interest on their debts. This, together with the reduced ability of prices to fall, which must result from the same more rapid increase in the quantity of money, would deprive them of any advantage of avoiding the fall in their money wages.

In reality, as we have seen, in a progressing economy, the quantity of money, volume of spending in general, and demand for labor in particular do all increase. As the result of the rise in the productivity of labor (and thus, one can presume, an increase in the quantity of money per capita), they increase not only absolutely but also relatively to the size of the population. And thus it is virtually impossible for falling wage rates to be the norm in such an economy. At the same time, however, the more rapid rate of increase in the quantity of money does serve correspondingly to raise the rate of profit and interest, including the rate of interest that wage earners must pay on any debts they incur, and it does serve correspondingly to diminish the rate at which prices fall. Thus while increases in the supply of labor do not actually serve to make wage rates fall from year to year, wage earners derive no permanent advantage from that fact.

PART C

UNEMPLOYMENT

1. The Free Market Versus the Causes of Mass Unemployment

It is now necessary to explain how mass unemployment can exist despite all that I have shown in Chapter 2 and in the first two parts of this chapter. That is, how it can exist despite a limitless need and desire for wealth and consequent inherent and ineradicable scarcity of labor, despite all the truths of productionism that follow from these facts, and despite the fact that, as Say's Law shows, all that is necessary for the creation of real demand is supply. Moreover, as I will show in Chapter 16, the process of production itself generates the monetary profitability that makes production financially worthwhile. It is necessary to show how mass unemployment is possible despite the existence of this fact as well.

There is a simple explanation that is perfectly consistent with all of these facts. It is that *unemployment is caused by an improper relationship between money wage rates and the demand for labor in the economic system*. Specifically, the average money wage rate is too high relative to the aggregate demand for labor. And since the aggregate demand for labor is determined by the quantity of money and the degree of saving in the economic

system, one can say that the problem of unemployment is the result of money wage rates that are too high in relation to these magnitudes, as well.⁶⁵

This explanation of unemployment is apparent in the formula I presented for the determination of the average level of money wage rates earlier in this chapter. Namely, that the average money wage of workers employed equals the aggregate demand for labor divided by the aggregate supply of labor, with the aggregate demand for labor being understood as manifested in a definite total expenditure of money to employ labor in the economic system, that is, in total payrolls of a given size, and the aggregate supply of labor being understood as manifested in a definite total quantity of labor employed. The formula, of course, is

$$W = \frac{D_L}{S_L}$$

And an illustration of it is

$$\text{\$10,000 per worker} = \frac{\text{\$1 trillion}}{100 \text{ million workers}}$$

The formula shows that with any given aggregate demand for labor, there is no limit to the number of workers that can be employed. All that is necessary is an appropriate level of money wage rates. For example, while a trillion dollar aggregate demand for labor employs 100 million workers at an average annual wage per worker of \$10,000, that same aggregate demand for labor could employ 200 million workers if the average annual wage per worker were \$5,000 instead of \$10,000. By the

same token, it could employ only 50 million workers at an average annual wage of \$20,000 per worker. The principle is that with a given aggregate demand for labor in the economic system, the number of workers that can be employed varies in inverse proportion to the average money wage rate per worker. Given the aggregate demand for labor as some definite amount of money, the division of that sum by any given average wage rate implies an inversely proportionate quantity of labor demanded.

When the demand for labor is diagrammed, as in Figure 13-4, the result is essentially the same as the productionist aggregate demand curve of Figures 13-2 and 13-3. Just as before, the demand curve is asymptotic, unit elastic, and potentially capable of purchasing an unlimited supply. And just as in Figure 13-3, under the freedom of competition what determines the actual quantity demanded and supply purchased, as opposed to the unlimited potential quantity demanded and supply purchased, is nothing but the supply that exists and whose owners want to sell it. Supply in this sense determines the quantity actually demanded—a quantity equal to itself—by virtue of its effect on the wage level, just as before it did so by virtue of its effect on the price level. Thus, as before, it “creates its own demand,” so to speak.

Figure 13-4 shows that one and the same aggregate demand for labor is capable of being accompanied by full employment in the face of any magnitude of supply of labor seeking employment. The supply of labor seeking employment is what is depicted by the vertical line *SS*. Although only one supply of labor seeking employment

Figure 13-4
The Demand For Labor

is depicted in Figure 13–4, it is clear that the line *SS* could be placed anywhere to the right and still be accompanied by full employment. This is because no matter how much the supply of labor seeking employment increases, the quantity of labor demanded becomes equal to it, provided only that the level of wage rates falls correspondingly. The supply of labor seeking employment becomes synonymous with the supply of labor employed by virtue of the necessary fall in wage rates, which serves to enlarge the quantity of labor demanded to equality with the supply of labor seeking employment.

Figure 13–4 also shows that with a given demand for labor and any given supply of labor seeking employment, it is possible to have not only full employment but also, alternatively, either mass unemployment or a labor shortage of varying degrees of severity. Which of these possibilities actually exists depends strictly on the relationship between the wage level and the demand for labor. At the wage level 1.0 on the vertical axis, the quantity of labor demanded along the aggregate demand curve *DD* is equal to the supply of labor seeking employment, which is represented by the line *SS*. Hence, at that wage level, full employment exists. Accordingly, on the horizontal axis I have marked the point directly below the intersection of *DD* and *SS* with the letter *F*, to indicate that that point represents full employment.

However, at the doubled wage level 2.0 on the vertical axis, which causes the quantity of labor demanded to be cut in half, namely, to $.5F$ on the horizontal axis, mass unemployment equal to 50 percent of the supply of labor seeking employment exists. On the other hand, at the halved wage level of $.5$ on the vertical axis, which causes the quantity of labor demanded to be doubled, to $2F$ on the horizontal axis, a severe labor shortage exists, with twice as many jobs being offered as there are workers to fill them.

To make the same point in terms of the example of a trillion dollar aggregate demand for labor and a supply of 100 million workers seeking employment: while an average annual wage rate of \$10,000 per year achieves full employment for this supply of labor, an average annual wage rate of \$20,000 per year results in a 50 percent unemployment rate, and an average annual wage rate of \$5,000 per year causes a labor shortage so severe that there are two jobs offered for every worker available to fill a job.

Thus, the difference between full employment, unemployment, and a labor shortage is a matter of differences in wage rates relative to the demand for labor. Depending on the height of wage rates, one and the same aggregate demand for labor is consistent not only with an unlimited potential quantity of labor demanded and thus with full employment no matter how large is the supply of labor

seeking employment, but also, as we now see, both with mass unemployment and, alternatively, with severe labor shortages. If wage rates are too high relative to the demand for labor, unemployment is the result. If they are too low, a labor shortage is the result.

Because of its great importance, a few further observations are in order concerning the aggregate demand for labor. Its constancy, indeed, its tendency to grow over time, is implied by the quantity theory of money. Its relationship to the demand for consumers' goods—and the wider relationship of the total demand for factors of production, that is, the demand for labor plus the demand for capital goods, to the total demand for goods, that is, to the demand for consumers' goods plus the demand for capital goods—is determined by the degree of saving in the economic system. Its relationship to the demand for capital goods is also determinate, but even in conditions in which the demand for labor might fall as the result of a rise in the demand for capital goods, the result is not against the interests of the average wage earner, as I have already indicated.⁶⁶ Furthermore, as we shall see, in the conditions of a depression and then of recovery from a depression, there is every reason for believing not merely that the demand for labor would remain constant in the face of a fall in wage rates, but that it would actually increase when the fall in wage rates took place and decline in the face of a failure of wage rates to fall!⁶⁷

Earlier in this book, I demonstrated the following points. The self-interest of buyers and sellers automatically operates to set prices and wages sufficiently high so that no shortages exist—so that, as I put it, quantities demanded are levelled down to equality with the supplies available. The setting of prices in this way is to the self-interest of buyers as well as sellers, and of poor buyers as well as rich ones. Shortages are created by government intervention into the economic system in the form of price controls, specifically, maximum price controls establishing legal ceilings, above which one is not allowed to sell. Shortages are exacerbated by the government's policy of inflation, which operates to raise the demand for the goods and services that are under price controls and which also creates the conditions in which price controls are imposed in the first place.⁶⁸

I will now proceed to show that the case of mass unemployment is essentially similar. In a free market the self-interest of buyers and sellers operates to set wage rates low enough to allow the quantity of labor demanded to expand to the point of equalling the supply of labor seeking employment and thus to prevent or quickly eliminate unemployment. This process is to the self-interest of wage earners as well as employers.⁶⁹ Mass unemployment, like shortages, is the product of the gov-

ernment thwarting the operation of the market participants' self-interest through a policy of price controls—this time, various forms of minimum wages establishing legal floors, below which one is not allowed to buy or sell labor. In addition, mass unemployment is precipitated by the government's policy of inflation—at the point where the inflation results in monetary contraction.

In a free labor market, the existence of unemployment automatically tends to reduce money wage rates to the level required to achieve full employment. This is because it is to the self-interest of the unemployed workers to offer to work for lower wages than those presently employed, in order to obtain jobs. At the same time, it is to the self-interest of employers to confront their present employees with the alternative of accepting a cut in wages or else replacement by presently unemployed workers. Thus, the competition of the unemployed workers for jobs and the self-interest of employers operate to bring down wage rates. The effect of the fall in wage rates, in turn, is to stretch the funds available for the employment of labor and thus to create new and additional job opportunities. For it increases the purchasing power of payrolls and thereby enables more workers to be employed with the same-sized payrolls. In this way, what may appear as a competition among workers for a given number of jobs has the effect of increasing the total number of jobs employers offer. (As we have seen, what is present here is actually nothing but Say's Law in the form of an additional supply of labor creating a corresponding additional real demand for labor by virtue of increasing the buying power of payroll funds.)

Of course, even with a fixed aggregate monetary demand for labor, the fall in wage rates would not produce proportionately more employment in each and every company or industry, but only in the economy as a whole. Just as with any other increase in production, people do not want proportionately more of each and every good with the increase in production due to the achievement of full employment, but very different additional quantities of the various goods. Hence, the reemployed workers are employed in different proportions among the various industries and companies than those who are already employed.

It is appropriate to observe here that while my analysis is carried on in terms of aggregates and averages, it is vital that the *individual* wage rates of all specific occupations and industries, in all their particular locations, be free to fall to the varying extents that are necessary. While isolated wage rigidities will not prevent the achievement of full employment, their effect is to require greater than necessary reductions in wage rates elsewhere and to cause unnecessary disproportions in the relative production of the various goods, and inefficiencies in the meth-

ods of production that are used. This is because those who are prevented from being employed in the lines where wage rates do not fall, or fall less than they would in a free market, must crowd into other lines, thereby further reducing wage rates in them. At the same time, production is artificially curtailed in the lines that maintain high wage rates (and high prices) and artificially expanded in the lines that bear a greater-than-necessary reduction in wage rates and prices. Insofar as this is the case with respect to the production of capital goods, the effect is that the supply of some capital goods is artificially held back, while the supply of others is artificially expanded. The effect is necessarily a lower productivity of labor as compared with what would exist with the appropriate proportions of the various capital goods.

Full Employment, Profitability, and Real Wages

It is important to realize two further points. First, consistent with the discussion of Say's Law and the average rate of profit earlier in this chapter, it should be understood that the fall in wage rates and prices needed to eliminate unemployment does not reduce the average rate of profit in the economic system. Increases in production do not reduce the average rate of profit whether they result from increases in the productivity of labor or from increases in the supply of labor, as in the present case. To show this, we can use the same example as before, in which the assumption of the full vertical integration of business was made for purposes of simplification. Thus, if the aggregate demand for consumers' goods in the economic system were fixed at 500 monetary units and the aggregate demand for labor at 400 monetary units, the amount of profit in the economic system would essentially be fixed at 100 monetary units, and thus, the amount of capital invested remaining the same, the average rate of profit in the economic system would remain the same.⁷⁰

This would be so irrespective of the number of workers employed for the 400 monetary units and irrespective of the resulting supply of goods produced and sold for the 500 monetary units. The fall in selling prices would not reduce the rate of profit because it would be preceded by a fall in unit costs to the same extent, based on the fall in wage rates. To state matters in an equivalent but more precise way, to whatever extent a larger output, in having to be divided into 500 of demand for consumers' goods, would reduce prices, that same larger output, in having to be divided into 400 of demand for labor, would reduce unit costs. At the same time, to whatever extent profit per unit was reduced, the increase in the number of units would precisely offset it, inasmuch as the fall in prices, unit costs, and profit per unit are all in inverse proportion to the increase in production and supply. The realization

that nothing is present to reduce the rate of profit in the process of achieving full employment is necessary in order to answer critics of the free market, above all, Keynes and his followers, who claim that the process causes a fall in the rate of profit and interest to a level so low that investment ceases to be worthwhile and the demand for money rises without limit.⁷¹

The second point that should be realized, and which is no less important, is that the fall in wage rates that is necessary to achieve full employment does not imply a fall in the standard of living of the average worker—that, indeed, even in the short run, it would almost certainly result in a *rise* in his actual standard of living, and would unquestionably do so in the long run. The reason is that the fall in wage rates would be accompanied by a fall in the prices of consumers' goods to the same extent, thereby leaving the purchasing power of the average worker's wages—his so-called real wages—unchanged. In addition to this, the achievement of full employment would mean the elimination of the burden of supporting the unemployed, whether they are supported through charitable contributions or through taxation. This is a burden which is always borne almost entirely by those who are employed, even when taxes to support the unemployed are levied on profits or interest.⁷² As a result, the fall in the prices of consumers' goods would tend to be *greater* than the fall in the average worker's "take-home" pay, thereby increasing the buying power of his take-home pay.

The conclusion that the fall in prices would be as great as the fall in wages follows on the basis of the formulas for the general level of wages and consumer prices. These formulas, once again, are

$$W = \frac{DL}{SL}$$

and

$$P = \frac{DC}{SC}$$

The conclusion follows on the basis of the continued assumption that the aggregate demands for labor and consumers' goods remain unchanged, coupled with the further assumption that the productivity of labor remains unchanged as the number of workers employed increases and full employment is achieved. The productivity of labor in the present context means the output of consumers' goods produced and sold per unit of labor employed. If it remains constant as the number of workers employed increases, then a larger supply of labor employed means proportionately more consumers' goods produced and sold.

On these assumptions, the employment of more work-

ers requires an inversely proportionate fall in wage rates. But the employment of more workers also results in a directly proportionate increase in the supply of consumers' goods produced and sold. Since the increase in the supply of consumers' goods produced and sold is in the same proportion as the increase in the supply of labor employed, it results in a reduction in prices that is in the same proportion as the reduction in wages, given that the aggregate demand for consumers' goods as well as the aggregate demand for labor is fixed.

For example, in the face of a constant demand for labor, the employment of ten-ninths the workers, to eliminate an unemployment rate of 10 percent of the labor force, causes wage rates to fall to nine-tenths of their initial height. Because the productivity of labor is unchanged, it also results in an increase in the supply of consumers' goods produced and sold that is in the ratio of ten-ninths. In exactly the same way that ten-ninths the supply of labor reduces wage rates to nine-tenths of their initial height in the face of a constant demand for labor, so ten-ninths the supply of consumers' goods reduces the prices of consumers' goods to nine-tenths of their initial height in the face of a constant demand for consumers' goods. Stated algebraically, using an asterisk to denote the fixity of the demands, we have:

$$\frac{9}{10} W = \frac{DL^*}{\frac{10}{9} SL}$$

and

$$\frac{9}{10} P = \frac{DC^*}{\frac{10}{9} SC}$$

Thus, the fall in prices is in the same proportion as the fall in wage rates.

Identically the same conclusion, that the fall in prices is as great as the fall in wage rates, follows on the view of cost of production as the determinant of prices. This is because if the productivity of labor remains the same, then a fall in wage rates implies a corresponding fall in the fundamental—labor—costs of production, and thus in prices.

I have said that the average worker's standard of living actually rises, by virtue of the elimination of the burden of supporting the unemployed, which has the effect of making the fall in his "take-home" pay less than the fall in prices. The following example illustrates this point. Thus imagine that in a state of mass unemployment, the average employed worker earns \$400 per week and contributes \$20 a week toward the support of the unemployed. As a result, his actual take-home pay is \$380. Now, as implied by a 10 percent fall in average wage

rates, imagine that the elimination of unemployment requires a drop of \$40 a week in his wages, which is accompanied by a 10 percent drop in the general consumer price level. His wage of \$360 now buys all that a wage of \$400 did before. However, this worker must actually be better off now than he was before. Because even though he used to earn \$400 a week, only \$380 of it was actually his to dispose of. For such a worker, therefore, the elimination of unemployment is accompanied by a fall in his take-home wages not from \$400 to \$360, but from \$380 to \$360, while prices fall in proportion to the fall in his gross wage rates from \$400 to \$360. In other words, while prices fall by one-tenth, our worker's take-home pay falls by only one-nineteenth. Thus, he is able to buy significantly more with his \$360 of take-home pay than he used to be able to buy with his \$380 of take-home pay.

There is really nothing surprising in the conclusion that the average previously employed worker comes out ahead, even though he earns less money. The conclusion does not depend on the choice of any specific set of numbers. It is implied in the very nature of things. Imagine, for example, a desert island which is inhabited by ten people. If one of them does not work and yet is to live, he must be supported by the labor of the other nine. If that individual now goes to work and supports himself, the standard of living of the other nine must certainly be improved, because now they will be able to keep for themselves the portion of their output which they used to turn over to him.

Exactly the same situation prevails in a modern economic system. What makes it difficult for most people to realize this is that almost everyone normally judges the economic effect of things exclusively in terms of their effect on money income and does not stop to consider their effect on prices. As a result, people are easily misled by the fact that the effect of the competition of a larger number of workers for jobs is a fall in the average money wage rate. What needs to be done to make one's thinking correspond to the facts, which are so obvious in the case of a desert island, is to realize that in the context in which the employment of more workers means lower wages, the sale of the products of those additional workers means proportionately lower prices. And thus the result is that the saving of the expense of supporting the unemployed works out to be a net gain.

What we have here, in other words, is another instance of the vital distinction that so often needs to be drawn between money value, on the one side, and actual physical wealth and the general standard of living, on the other. The two can go different ways in the context of the economic system as a whole, and we must not be misled into thinking that merely because something may operate

to reduce the average money income that is earned, it therefore operates to reduce the physical wealth that is obtained and the standard of living that is enjoyed.

Some economists argue that a condition of restoring full employment is a *drop* in real wages—a fall in prices that is less than the fall in wage rates.⁷³ The basis for this conclusion is the belief that the employment of more workers will be accompanied by the operation of the law of diminishing returns, as more labor is applied in conjunction with a given, existing quantity of plant and equipment. As reemployment occurs, plant and equipment will have to be worked more intensively. It will also be necessary to bring back into use older, less efficient plant and equipment that was idle during the depression. As a result of these circumstances, it is held, the increase in output will be somewhat less than proportionate to the increase in the supply of labor employed, and thus the fall in prices will be less than proportionate to the fall in wage rates.

In addition, it is held, there must be a recovery in profits, which are all but wiped out in the depression. And thus, for this reason, too, it is argued, the fall in prices will be less than proportionate to the fall in wage rates. Indeed, to cast this argument in terms of our supply and demand formulas and the discussion of the relationship between profits and net investment that will come in Chapter 16, it could be argued that recovery requires an increase in the proportion of workers employed in the production of plant and equipment, which proportion was sharply reduced during the depression. As a result, some significant part of the output of the reemployed workers will be retained within business enterprises and not show up in the current supply of consumers' goods, thus further limiting the fall in prices relative to the fall in wage rates.

Now the first thing that must be observed in connection with these arguments is that even if they were correct, all they would imply is that the fall in money wage rates necessary to eliminate unemployment would be accompanied by a fall in real wage rates no further than to approximately the level prevailing before the depression. The arguments about diminishing returns and the restoration of profitability imply that during the depression, the real wages of those fortunate enough to retain their jobs are artificially increased by virtue of those workers being able to work only with the newest, most productive plant and equipment, and by virtue of the consumption of capital. Thus the arguments imply that with recovery, and the elimination of those factors, the real wages of those who had retained their jobs merely fall back to a more normal level.

Secondly, it should be realized that even if these

arguments were correct, the fall in real wages accompanying the restoration of full employment would be of a temporary nature only. It is not possible for real wages to be elevated permanently on the basis of unemployment and capital decumulation. The restoration of full employment and the end of capital decumulation—the resumption of positive capital accumulation—means that as time goes on, better and better grades of plant and equipment will spread to the whole labor force, whose productivity will be raised correspondingly, with the effect of raising the average level of real wage rates to the same extent.⁷⁴ And, because full employment represents the use of a substantially larger labor force as compared with mass unemployment and thus makes possible a significantly greater division of labor, it will itself help to make possible the on-going rise in the productivity of labor that is attributable to a greater division of labor.⁷⁵

Thus, even if real wages did have to fall with the restoration of full employment, the fall in money wage rates would still be to the long-run material self-interest of the average wage earner. This is so because not only would unemployment be eliminated, thereby eliminating the burden of supporting the unemployed, but also the assumptions of the case imply that the fall in real wages is necessary to the maintenance and increase in the supply of capital goods, and to the division of labor being carried to a greater extent, which also promotes capital accumulation.⁷⁶ These developments are necessary to increases in the productivity of labor and thus real wages in the future. Higher real wages today, obtained at the cost of capital decumulation or the failure to accumulate substantial additional capital goods that otherwise could have been accumulated, and at the closely related expense of the extent to which the division of labor is carried, cause real wages in the future to be lower or to increase by less.

However, the argument that diminishing returns and the restoration of profitability imply a fall in real wages, is by no means correct even in application to the short run. It overlooks both the elimination of the burden of supporting the unemployed and the fact that the approach to full employment is probably accompanied by a *rise* in the average productivity of labor, despite the operation of the law of diminishing returns in connection with a given stock of plant and equipment. This is because the increase in production takes place mainly in accordance with the increase in the employment of *direct*—i.e., “blue-collar”—labor, and thus tends to be more than in proportion to the increase in the *total* supply of labor employed.

As illustration of this point, imagine that in a state of mass unemployment, for every ten direct, blue-collar

workers working, there are ten overhead, “white-collar,” administrative-type workers working. Now, with full employment, there are twenty direct workers working for every ten overhead-type workers working. Thus, putting aside diminishing returns for the moment, *output doubles with less than double the labor*—with only three-halves the total labor employed. The principle that the overall average productivity of labor rises with recovery from a depression is not affected if, because of the operation of the law of diminishing returns, output increases somewhat less than in proportion to the increase in the employment of direct workers, which would fully satisfy the conditions of the law of diminishing returns. Nor is it affected by the probable need to employ some additional overhead-type workers along with the additional direct workers. It holds so long and insofar as the unemployment is more heavily concentrated in the blue-collar ranks than in the white-collar ranks (which is usually the case) and output increases basically in accordance with the increase in blue-collar employment.⁷⁷

Furthermore, the rise in the average productivity of labor that occurs is compatible with prices falling less than costs, to allow a recovery in profitability, and yet as much as or even more than wages, which also fall by less than costs. For example, wages might fall by 10 percent, costs by 15 percent (because of the increase in the average productivity of labor as well as the fall in wage rates), and consumers’ goods prices by 12 percent. The fall in prices here is less than the fall in costs, which allows an increase in profitability, and yet greater than the fall in wages. Indeed, this very sort of phenomenon can be seen to have taken place in the recovery from the recession of 1982 in the United States. In that recovery, the reduction in unemployment was accompanied by the first rise in real wages to have taken place in many years.

But even if real wages did have to fall to make possible the restoration of full employment, then, as I have shown, the process would still be to the long-run self-interest of the employed workers, not to mention the self-interest of the unemployed workers, who would once again have jobs.

It should be realized that the fall in prices that accompanies the fall in wage rates in the process of eliminating unemployment greatly mitigates any greater difficulty in repaying debts that might be experienced by workers whose wages fall. And when the effect of the elimination of the burden of supporting the unemployed is taken into account, it is probable that in most cases, any greater burden of repaying debt is more than offset.

This conclusion can be understood in the light of our example of the fall in the wages of the average worker from \$400 per week to \$360 per week. Let us imagine that such a worker has to make debt payments and meet

other fixed obligations, such as a lease, that average \$100 per week. In that case, the funds he initially had available for meeting his other expenses were \$300 per week—actually, \$280 per week, when the burden of supporting the unemployed is taken into account. Now, with the fall in his income to \$360 per week and the elimination of the burden of supporting the unemployed, he has \$260 a week to spend as he wishes. This sum, of course, is \$20 less than the amount he initially had available for purposes other than meeting fixed obligations. However, with the fall in prices of 10 percent, the buying power of these \$260 is the equivalent of significantly more than that of the initial \$280—in fact, it is equal almost to that of \$289 in terms of the initial, lesser buying power of money, for at nine-tenths the prices, the buying power of any given sum is ten-ninths as great, and ten-ninths of \$260 is approximately \$289.

Moreover, even the fixed obligations of the workers are not permanently fixed. Within one to three years, practically all apartment leases come up for renewal, and in that time these fixed obligations come to be restated in accordance with the lower prevailing level of prices. In addition, within this time, many debts are paid off, such as most installment loans, and are replaced with smaller debts that represent equivalent buying power. Even mortgage payments can be reduced to correspond to the fall in prices, once a homeowner refinances his home at a lower rate of interest or sells his present house and buys another, equivalent house at a lower price. (As this last observation suggests, perhaps the only case of significant loss of buying power for wage earners occurs not in their capacity as wage earners but as homeowners, whose equity may be sharply reduced or wiped out by the fall in the price of houses. Of course, this loss in many cases is the loss merely of an equity that was created by preceding inflation.)

Finally, whatever additional debt burden, if any, the fall in wage rates might place on wage earners who already had jobs, it certainly does not place any additional debt burden on all wage earners taken together—those who were unemployed before the fall in wage rates, as well as those who had jobs. Before the fall in wage rates, the incomes of the unemployed workers were zero, which meant that they had absolutely no earnings with which to pay their debts. The fall in wage rates of the workers already employed is the foundation of a rise—the coming into being—of the wage rates of the workers who were unemployed and is the basis of their being able to pay their debts. Any greater debt burden on wage earners as a whole is not imposed by a fall in wage rates, which, in eliminating unemployment, at most serves to increase the debt burden of some wage earners while reducing that of others, but by a fall in the aggregate

demand for labor, which, of course, is also what precipitates mass unemployment. A fall in the aggregate demand for labor means a reduction in the total of the wages paid in the economic system, and, in the face of a given magnitude of debts on the part of wage earners, necessarily makes the repayment of those debts more difficult. Thus, the actual damage to the ability of wage earners as a group to pay their debts is done before the fall in wage rates. It is the result of a financial contraction.⁷⁸

The fall in wage rates, as I say, at most merely redistributes the greater debt burden. And, as I have shown, in the process it actually improves the economic situation of the wage earners to whom the debt burden is transferred, by virtue of bringing about full employment and thus the elimination of the burden imposed on these workers of having to support the unemployed, while at the same time reducing the prices these workers must pay. And then, of course, following the fall in wage rates and prices, with the passage of time and the replacement of expiring debt contracts with new ones made in accordance with the lower level of prices, the greater debt burden is eliminated altogether. In addition, the greater division of labor and resumption of capital accumulation or more rapid capital accumulation that goes with full employment in a free market operates progressively to raise the productivity of labor and real wages. In sum, when unemployment exists, a fall in wage rates is a necessary and benevolent phenomenon that eliminates the unemployment and operates to raise the general standard of living.

A case in which the fall in wage rates necessary to eliminate unemployment might actually reduce the average level of real wages in a country is that of a relatively small country whose citizens are confined to the narrow labor market of their own country by other countries' immigration barriers. To the extent that the fall in wage rates in such a country achieves full employment by reducing the costs of production and prices of its exports, it is the real wages of workers in other countries that are increased. In this case, however, there is present not only the at least partially offsetting beneficial effect of eliminating the burden of the unemployed, but also the incentive to additional foreign investment in the country that is provided by its lower level of wage rates. And, of course, the workers of the country benefit from all wage reductions in foreign countries insofar as they lead to lower prices of imports into the country.

This case appears to fit present conditions in Ireland, for example, where there is a substantial unemployment rate. Ireland could achieve full employment by means of a fall in its wage rates, which in large part would make its exports more competitive and so expand employment

in its export industries. However, for the reasons explained, the effect would be a fall in real wages in Ireland until such time as wage reductions abroad and the resulting decline in the price of imports into Ireland came into play.

This case has bearing on the conditions within particular industries and regions in countries of any size. Always the effect of wage cuts and the resulting reductions in costs of production and prices is to raise the real wages of the workers who buy the product. The rise in the real wages of the workers who help to produce the product depends on the fall in wage rates and costs of production and prices in the industries whose products these workers themselves buy.

Government Interference

It should be obvious from our discussion of how the free market operates to establish full employment that what is responsible for unemployment is government interference with the operations of a free market, specifically, interference of the kind that prevents unemployed workers and employers from pursuing their self-interest. Such interference, in the form of attempts to increase or maintain the level of money wage rates, forcibly holds the level of money wage rates too high relative to the aggregate demand for labor and thus prevents the number of jobs offered from coming up to equality with the number of jobs sought. Minimum-wage laws and laws giving labor unions the power to force employers to accept artificially high union pay scales are leading examples. These laws push up or keep up wage rates and make the existing aggregate demand for labor inadequate to employ all the workers seeking employment. Unemployment insurance and welfare allowances that are high enough to be competitive with the wages that workers can earn also contribute to unemployment, by virtue of taking away the incentive to seek work.

The effect of these kinds of interference is greatly compounded by further government interference of the kind described in the last chapter, which has the effect of causing monetary contractions and thus actual reductions in the aggregate demand for labor on a large-scale. When this happens, a fall in money wage rates is made necessary in order to maintain the previous level of employment. But government interference with wage rates and with the incentives to work prevents the necessary fall, and so turns the reduction in the aggregate demand for labor into a cause of permanent mass unemployment.

The government interference that causes monetary contraction is, of course, the previous adoption of a policy of inflation—i.e., an increase in the money supply at a rate more rapid than the increase in the supply of

precious metals—above all, the policy of encouraging credit expansion and the creation of fiduciary media.⁷⁹

The effect of this policy is to cause demand of all types, including the demand for labor, to increase to a level that can be sustained only by the continuation, indeed, only by the acceleration of the inflation. When the inflation is stopped, significantly slowed, or even merely fails to accelerate sufficiently, a contraction in spending develops.

In effect, inflation operates like a narcotic, whose stimulative effect requires increasing doses. If the narcotic is cut off, or available only in lesser quantity, or even just in insufficiently increased quantity, there is a crash. Inflation has these effects because it induces people to overextend themselves financially, in the expectation of gaining from the effects of further inflation.⁸⁰

As we have seen, once underway, a monetary contraction can be accompanied, and greatly intensified, by an actual deflation of the money supply—that is, by an actual reduction in the quantity of money. This occurs as the result of a substantial number of borrowers becoming unable to repay debts to banks. Inflation and credit expansion had encouraged them to borrow heavily, in the expectation of gaining from the fall in the value of money caused by inflation, and from the rate of profit and rise in prices continuing to outstrip the rate of interest they had to pay, which was artificially held down by credit expansion.⁸¹ When this turns out no longer to be the case, people find that they are saddled with debts that they cannot pay.⁸² Their default on debts to banks then destroys the solvency of various banks, with the result that such banks cannot honor their deposits. Insofar as the deposits in question are checking deposits, the effect is a reduction in the quantity of money. Checking deposits held at a solvent bank are a means of payment, just as much as currency and coin. Checking deposits held at an insolvent bank have more in common with Czarist bonds. They cannot be used in making payments. As a result, as banks fail, the quantity of money is actually reduced.⁸³

As we know, this causes a further contraction in spending, greater difficulties in repaying debts, and still more bank failures. Potentially, the process could go on until all of the debt-backed money supply—all the fiduciary media—had been eliminated, and all that remained was standard money—that is, money that is not a claim to anything else, but is itself the means of final payment, such as gold coin or bullion on a gold standard.⁸⁴ This appears to have been on the verge of happening in the banking crisis of 1933.

Knowledge of the fact that unemployment can be eliminated by virtue of a fall in wage rates and prices, and that government interference is what prevents this,

implies that there is absolutely no necessity for any kind of “trade-off” between inflation and unemployment, as is claimed by the supporters of the so-called Phillips curve.⁸⁵ In a free market, full employment is achievable precisely by means of a *fall* in wage rates and prices. The Phillips curve analysis, however, is so imbued with the spirit of government intervention and Keynesianism that it is blind to the very possibility of this occurring. In effect, in terms of the most elementary supply-and-demand analysis, it fails to see how increases in quantities bought and sold can be achieved from the side of supply, at lower prices. It assumes that increases in quantities bought and sold originating on the side of supply are simply impossible and that only increases originating on the side of demand are possible. Only in that way can it arrive at the notion that a reduction in the unemployment rate must be accompanied by rising prices. As we shall see, where government interference makes it impossible to eliminate unemployment by means of a fall in wage rates and prices, it is also not possible to eliminate unemployment by means of increases in demand—that is, by means of increases in the quantity of money and volume of spending in the economic system.⁸⁶

2. Unemployment and the 1929 Depression

We now know that monetary contraction is the precipitating cause of mass unemployment, which is then perpetuated by government interference in the labor market, which prevented the fall in wage rates necessary to eliminate the unemployment. In the early 1930s, the United States did not have a federal minimum-wage law. And the labor unions, although already extremely powerful in the construction and railroading industries, were not nearly as widespread as they were later to become. Nor were the incentives to avoid seeking work nearly as powerful as they were later to become. Nevertheless, in this period, the federal government, under President Hoover, actively intervened against a fall in wage rates, and at a series of White House conferences obtained the agreement of the leading businessmen of the country not to reduce wage rates. Hoover, along with a majority of the businessmen of the time, naïvely believed that a fall in wage rates was equivalent to a fall in total wage payments and would thus result in a reduction in consumer spending and a deepening of the depression.⁸⁷ This mistaken belief was the reason he intervened against falling wage rates. Hoover’s intervention was reinforced by the influence of the philosophy of altruism insofar as that philosophy played a role in the decisions of businessmen. For altruism too implies that employers should not take advantage of the existence of unemployment to reduce wage rates.⁸⁸

The effect of such interference was that the fall in wage rates took place at a much slower rate than in any previous depression. Average wage rates dropped less than 2.5 percent in 1930 and only about 6.5 percent in 1931.⁸⁹ In contrast, they had dropped 19 percent in one year in the depression of 1920–21, which was extremely short-lived as a result.⁹⁰

The effect of the failure of wage rates to fall was an unnecessary deepening of the depression, requiring a much greater fall in wage rates to restore full employment than would have been necessary if they had been allowed to fall right away. This was the case because businessmen who contemplated investments in plant and equipment and inventory accumulation had to realize that until wage rates fell, the level of construction costs and inventory acquisition costs was substantially higher in the present than it was likely to be in the future, with no compensating advantage of lower costs in the present compared with the past.⁹¹ As a result, businessmen had a powerful incentive to postpone such investments—and did postpone them. Investment spending for plant and equipment and the net change in business inventories fell by 37 percent in 1930, by 45 percent in 1931, and by 83 percent in 1932!⁹²

This collapse in investment spending and inventory holdings, because of the failure of wage rates to fall, caused a virtual wiping out of business profitability. The wiping out of business profitability ensued because the collapse in plant and equipment spending meant a corresponding reduction in business sales revenues in the economic system, while depreciation costs, reflecting the plant and equipment spending of many prior years, could hardly fall at all. Similarly, the drop in spending for inventory and work in progress also meant a corresponding decline in sales revenues in the economic system. But cost of goods sold continued to reflect the higher outlays for inventory and work in progress made in previous years, and thus fell only with a lag.⁹³ As a result, with sales revenues reduced far more than the costs deducted from those sales revenues, profits were slashed in tandem with the fall in investment.

With the decline in sales revenues and profits came a corresponding diminution of the ability of business firms to repay debt. Thus, as a further result, bank failures were precipitated which otherwise need not have occurred. The deflation of the money supply caused by these bank failures, of course, resulted in further declines in the volume of spending, and thus in more unemployment and in a need for a still greater decline in wage rates if full employment were to be restored.

In creating the prospect that investments made in the present would be at a major competitive disadvantage with investments made in the future, the effect of the

failure of wage rates to fall, or to fall sufficiently, was to block a major source of the inherent profitability that exists in a free economy in the form of virtual “springs to profitability,” as it were, whose nature I will explain later in this book. Had wage rates fallen to their equilibrium level, so that there would have been no problem of investments made in the present being at a competitive disadvantage with investments made in the future, then, as we shall see, the very fact of the absence of profitability, or its unduly low rate, would itself have provided an impetus to an increase in the degree of capital intensiveness in the economic system and thus to stepped up investment and thereby the restoration of profitability. It could not do so, however, in an environment in which more-capital-intensive investments made in the present were also likely to turn out to be losing propositions in competition with more-capital-intensive investments made in the future.⁹⁴

It should be observed, of course, that an important implication of the fact that until wage rates fall to their equilibrium level, investment spending is postponed, is that when wage rates do fall to their equilibrium level, *the demand for labor actually increases*. This is because at that point investment spending is restored. An important implication of this increase in the demand for labor, in turn, is that it is actually a mistake to look at the level of total payroll spending in the depths of a depression and to assume that the fall in wage rates necessary to achieve full employment must be such as to permit the full number of workers to be employed with that level of payroll spending. Actually, the necessary fall in wage rates is substantially less than this, because the fall in wage rates to the point of full employment will be accompanied by a rise in total payroll spending in conjunction with the decline in the demand for money that occurs as the result of the restoration of the competitiveness of investments made in the present with investments made in the future.

With the restoration of investment spending, of course, comes a restoration of general business profitability as well. For business sales revenues now rise relative to depreciation costs and cost of goods sold. Thus, the fall in wage rates to their new equilibrium level is the foundation not only of the restoration of full employment, but also of investment spending and general business profitability.⁹⁵

3. Unemployment, the New Deal, and World War II

I have explained how government interference in the early 1930s prevented a fall in wage rates from eliminating unemployment and thus deepened the depression and greatly intensified the problem of unemployment. The

monetary contraction which represented the onset of the depression was also the product of government interference, as I have shown.⁹⁶ Specifically, it was the product of the expansionary monetary policy of the Federal Reserve System and foreign central banks in the 1920s, which built on a base laid by the massive inflations of World War I. This led to a rise in the velocity of circulation of money, which could be sustained only by the continuation—indeed, ultimately, only by the acceleration—of inflation and credit expansion. It also led to the incurrence of an even greater increase in the volume of debt, because inflation in the form of credit expansion holds interest rates at an artificially low level relative to the higher rate of profit and the rise in prices it causes. It thus encourages people to contract larger volumes of debt relative to their already artificially increased revenues, incomes, and asset values.⁹⁷ In addition, the process of inflation and credit expansion leads to numerous malinvestments—investments whose profitability is created and exists only so long as the inflation and credit expansion continue or accelerate.⁹⁸ Finally, the potential for the actual deflation of the money supply was also created by government interference—interference in support of fractional reserve banking, in order to make credit expansion possible. This form of interference spanned generations, as previously explained.⁹⁹ Having thus created all the necessary potential for a monetary contraction, that potential was actualized by the Federal Reserve’s return to a very modest 1.1 percent compound annual rate of increase in the money supply between June 1925 and June 1929.¹⁰⁰

Starting in 1933, with the New Deal and the overthrow of the gold standard, the government was able to inaugurate a policy of permanent inflation. Since 1933, the quantity of money and the total volume of spending in the economic system—including, of course, payroll spending—has increased significantly in almost every year. Despite the rise in payroll spending, mass unemployment continued in the United States until the country’s entry into World War II. It did so, because the far more powerful labor-union movement created under the New Deal was able to increase wage rates at a substantial rate even in the midst of mass unemployment, with the result that the larger payrolls achieved by inflation could not employ correspondingly more labor or, indeed, enough additional labor to make any major headway in eliminating unemployment. (The rates of increase in average annual wages paid by private employers for the years 1934 to 1937 were 5.7 percent, 4.9 percent, 5.6 percent, and 8.3 percent respectively.¹⁰¹) Thus, while approximately 12 million workers were reported as unemployed in 1932, and 12.8 million in 1933, the numbers for 1934–1940 were not radically reduced. Indeed, when the

substantial numbers of workers employed by the government in various artificial work-relief programs are added to the number of workers reported as openly unemployed, the unemployment record turns out to be as follows: 1933: 13.5 million; 1934: 12.7 million; 1935: 12.1 million; 1936: 11.4 million; 1937: 9.3 million; 1938: 12.5 million; 1939: 11.5 million; 1940: 9.9 million.¹⁰²

The increase in union power began with The Norris-La Guardia Act of 1932, passed in the final year of the Hoover administration. This act prohibited the granting of federal court injunctions against mass picketing and other forms of union coercion. It was followed by the National Industrial Recovery Act of 1933, which was subsequently declared unconstitutional but whose provisions dealing with labor were reinstated in the Wagner Act of 1935. This legislation compelled employers to recognize labor unions and to bargain with them. These laws were the basis of the unionization of such major industries as steel, automobiles, coal, rubber, clothing, meatpacking, and cement. Their result was to compel even most nonunion employers to match union wage increases, lest they too be unionized and end up not only having to pay the higher union wages but also lose much of their ability to determine methods of production. The Fair Labor Standards Act of 1938 established a federal minimum wage. Thus, prounion legislation and minimum-wage legislation substantially raised wage rates in the midst of mass unemployment and thereby prevented the larger payrolls produced by inflation from substantially reducing, let alone eliminating, unemployment.

Furthermore, insofar as the additional employment which resulted in connection with the policy of inflation was employment on government projects, or in providing the materials and equipment for such projects, it did not represent any real solution to the unemployment problem, as I have indicated. Indeed, it represented an actual *loss* to the workers producing in the rest of the economic system, who had to support it. The workers in the rest of the economic system had to supply goods and services to the workers newly employed in connection with government projects—substantially more goods and services than would have had to be provided if those workers had remained unemployed. This is because they had to supply them with a higher standard of living than the newly employed workers would have received had they remained unemployed. In addition, they had to supply them with materials and equipment with which to work, which would not have been required had those workers remained unemployed. But all that the workers in the rest of the economic system could receive from those newly employed workers was *the government projects*, which were undertaken not because of any actual value on their part but because of a desire to create

employment. In the circumstances, the projects could not constitute compensation to those whose goods and services had to pay for them. In effect, a broken circle existed: part of the output of those already employed—a greater part than before—was turned over to those newly employed, but the output of the newly employed went to the government and thus could not constitute compensation to those already employed. In effect, it was a case of Mr. A giving employment to Mr. B, and sending the bill to Mr. C. The last individual, Mr. C—the mass of the general public—necessarily lost by such an arrangement.

(As an example of this phenomenon that I give to my students, I ask them to imagine that our class constitutes an economic system and that the students in the front row are unemployed. I assume the role of the government and offer to employ those students in doing various jobs for me. In a closed economic system, the rest of the class is the only possible source of goods and services for these reemployed students. Thus, in one way or another it will be billed for their employment. I point out how much greater its bill will be if I employ the previously unemployed students in a project that requires the use of substantial materials and equipment, such as building a house for me.)

Thus, to the extent that it exists, the effect of government-caused reemployment is to reduce the standard of living of those already employed. This is in sharpest contrast to the effect of reemployment achieved by the competition of a free market, which is to eliminate the burden of supporting the unemployed. In a free market, an unemployed worker gets a job and supports himself. Under government make-work schemes, the previously unemployed worker becomes a greater burden than before.

The problem of mass unemployment came to an end with the country's entry into World War II. This happened not because, as the consumptionists believe, the war created new and additional needs and desires for wealth. As I have shown, for all practical purposes the need and desire for wealth are always infinite. It did not even happen because the war was largely financed by a massive creation of new and additional money. In a context in which monopoly labor unions and other government intervention prevent unemployment from being eliminated by a fall in wage rates, the same forces operate to cause a rise in wage rates in the face of a rising demand for labor and thus to make the rising demand for labor incapable of eliminating the unemployment.

Why Inflation Cannot Achieve Full Employment

As I have just indicated, in a context of powerful monopoly labor unions, inflation of the money supply, by itself, cannot achieve full employment. This is be-

cause it removes the brake on union demands for higher wages. Its very existence makes it possible for the unions to pursue their policy of raising wage rates, even in the midst of mass unemployment, because it puts them in the position of being able to do so without fear of causing still greater unemployment of their members. For, with inflation, employers have the necessary funds to pay higher wage rates to an unchanged number of workers, and buyers of products have the necessary funds to buy an unchanged quantity of output at the higher prices corresponding to the higher wage rates. In addition, the unions are encouraged in their demands because, as we have seen, the spending of a larger quantity of money operates to increase nominal profits. The rise in profits operates as a red flag to the unions, signalling an automatic justification in their eyes for a rise in wage rates. Finally, as soon as the increase in the quantity of money and volume of spending begin to raise prices—whether because they encounter goods available only in limited quantity, whose prices must rise in the face of an increased demand, or because they lead to a rise in wage rates and thus costs of production, in the ways just described—the unions feel entitled to demand wage increases to keep pace with the price increases. For these reasons, in a context in which a fall in wages and prices is prevented from achieving full employment, a policy of inflation by itself also cannot achieve full employment.

Inflation Plus Price and Wage Controls

What made it possible for World War II to be accompanied by the restoration of full employment was not even the drafting of more than twelve million men into the armed forces, though this did make some contribution. For insofar as these men had jobs and were supporting, or helping to support, families before our involvement in the war, their disappearance from the labor market necessarily caused large numbers of women and youths to enter the labor market in order to serve as substitute breadwinners. The reason there was a larger total number of jobs available when these groups entered the labor market was the combination of a policy of massive inflation coupled with *wage and price controls*.

The effect of this combination was that when inflation raised the demand for labor and products, wage and price controls prevented a corresponding rise in wage rates and prices. Thus, the larger volumes of spending for labor and products were able to purchase larger quantities of labor and products. Indeed, very quickly, mass unemployment and a situation of unsalable goods was transformed into an actual *shortage* of labor and products. In this way, the war did solve the unemployment problem. It did so in accordance with the same principle on which the problem could have been solved *without a war*—namely, a

fall in wage rates and prices relative to the volume of spending for labor and goods.

This relative fall could have taken place in peacetime, without inflation, by means of free competition serving to reduce wage rates and prices absolutely in the face of a slowly increasing quantity of money. Instead, it took place in wartime, by means of the combination of inflation and wage and price controls, which achieved the necessary relative fall in wage rates and prices by means of a rapid increase in the quantity of money coupled with forcible restraint on the ability of wage rates and prices to rise.

Thus, the war was not at all necessary to achieve full employment. Its only economic contribution was that it served to nullify the destructive peacetime government interference in the labor market that had prevented the achievement of full employment, namely, the fixing of wage rates too high in relation to the demand for labor. It did this in the course of unleashing far greater, far more destructive government interference in the economic system and in people's lives generally, which is the inevitable accompaniment of any major war. How much simpler it would have been to achieve full employment by openly repealing the peacetime government interference in the labor market and avoiding the war. One may think of the government's peacetime interference in the labor market as the equivalent of forcing someone to wear a pair of shoes that is several sizes too small and thus extremely painful. The obvious, simple way to solve the problem is to stop forcing the person to wear that pair of shoes and to let him choose his own pair of shoes. War as a means of eliminating unemployment, through the combination of inflation and price controls, is comparable to the government making the wearer's feet fit the wrong pair of shoes by means of chopping off part of his feet. And to this, of course, must be added all the grosser dismemberments and destruction of life and property that are the literal accompaniment of war.

World War II as the Cause of Impoverishment in the United States

The fact that World War II was accompanied by the restoration of full employment does not mean, as is so often believed, that it was a period of prosperity. While some people were rendered materially better off, the immense majority were severely impoverished. As we have already seen, as the result both of the wholesale prohibition of major categories of civilian production, in order to concentrate on war production, and of shortages of practically all civilian goods that were still allowed to be produced, the standard of living of the average American family during World War II was reduced to a point far below its level in the worst years of the depression.¹⁰³

As in the case of government make-work schemes in peacetime, any additional employment achieved by the government in wartime is at the expense of the great majority of people who are already employed. From their perspective, such additional employment is always a case of their having to pay the bill for the additional employment, in terms of the part of their output that they turn over to the reemployed or provide to them in the form of materials and equipment, and for which they receive no compensating output because the goods and services of the reemployed are of minimal economic value or altogether economically useless, which last is certainly the case when the output is war goods.

An additional aspect of the reduction in the standard of living of the great majority of the American people was the fact that people worked longer and harder during the war and, as I have indicated, many people found it necessary to work who otherwise would not have found it necessary to work, such as many housewives, high school students, and retirees. As shown, despite all extra work, the average family received much less than it did before the war. This was the inevitable result of the economic system being made to produce for the war. If roughly half the net output of the economy goes for the war, as it did in World War II, then the most that can remain for the producers is roughly half of the net product of their labor. Such a situation means that the average family must have less and work more, in order not to have too much less.

As we have also seen, during the war most people did not realize how much worse off they actually were, because people usually measure their well-being in terms of the money they earn or their property is worth. The massive creation of money during the war increased practically everyone's money income and the money value of his assets. People simply didn't stop to think that much of the money they earned was unuseable for anything but the purchase of government bonds, or the accumulation of savings accounts invested in government bonds. In addition, as I explained in my discussion of universal price controls in Chapter 7, the very existence of shortages contributed to a delusion of prosperity during the war. Under shortages, nothing more is required of a businessman than that he succeed in delivering to the market some semblance of what his product is supposed to be, because the buyers will snap up practically anything that has greater utility than the otherwise unspendable paper money. By the same token, anyone can quickly find employment who fulfills even the most minimal requirements of a job.¹⁰⁴

And, finally, it should never be forgotten that the full employment of World War II was accompanied by a profound threat to the freedom of employment, owing to

the chaotic conditions that always accompany a shortage of labor. This threat, of course, was expressed in President Roosevelt's proposal of forced labor in the United States, in his 1944 State of the Union Message.¹⁰⁵

Prosperity Based on the Return of Peace

While the war was accompanied by full employment under conditions of impoverishment, full employment under conditions of *prosperity* was made possible only by *the return of peace*. The restoration of peace made possible a radical reduction in government spending and thus in the portion of the output of the economic system absorbed by the government. It put an end to the government's massive printing of money to buy up output and correspondingly reduce the output remaining to the citizens, who had produced the output. Between 1944, the last full year of the war, and 1946, the first full year of peace, federal government spending was reduced from \$100 billion (which equalled more than half of the net national product of the time) to \$38 billion, and approximately eight million soldiers and sailors were discharged.¹⁰⁶

The reduction in government spending made possible a corresponding increase in private spending to the extent that taxes were slashed and the funds previously going to the purchase of government bonds likewise became available for private use. The government's spending for tanks, planes, and artillery shells was replaced by private spending for passenger automobiles, houses, and all kinds of other civilian goods, whose physical production was made possible by the fact that labor and capital were no longer required to produce the war goods. Of course, the returning soldiers and sailors also greatly contributed to the rise in the standard of living of the average family, insofar as their labor did not merely take the place of the labor of other family members but was added to it or represented more productive labor. This made possible an increase in the total volume of production. The abolition of wage and price controls following the end of the war eliminated the shortages and inefficiencies they had caused, and thus it too powerfully contributed to an increase in the overall volume of production and rise in the standard of living.

The end of wage controls was not accompanied by any substantial increase in unemployment. This was because the return to peace made possible a vast increase in private employment and rise in the general standard of living not only in the ways I have described, but also by virtue of increasing the capital funds in the possession of business firms. Thus, when government spending fell and demand shifted from war goods to peacetime goods, business did not simply shift a given amount of capital funds from war production to peace production. On the

contrary, the total amount of capital funds in its possession increased, as the result of sharp reductions in its tax burden and in the drain of funds into the purchase of government bonds. Thus, business was in a position to increase its overall demand for labor and capital goods. The return to peace, therefore, meant a rise in wage payments relative to consumer spending, and a rise in the demand for, and production of, capital goods relative to consumers' goods. Our discussion of the determinants of real wages and the general standard of living in the next chapter will show that no development could be more conducive to raising the general level of real wages and to enabling them to go on rising.¹⁰⁷ In this context, major increases in wage rates, both nominal and real, could take place without causing unemployment or higher prices. At the time, and thereafter, the unions followed their normal, relatively conservative policy of seeking increases in real wages only modestly above those provided by the market. Such increases can, of course, gradually produce a substantial rate of unemployment over a period of years, and should not, therefore, be dismissed as unimportant. But the contribution of the labor unions to an immediate problem of mass unemployment is generally in the context of a depression, when the demand for labor sharply falls and the unions refuse to allow corresponding reductions in money wage rates.

A Rational Full-Employment Policy

Governments all over the world are concerned with policies designed to achieve or maintain full employment. To achieve this end, they typically enact policies of inflation, public works, featherbedding, and, indeed, war. But this chapter points to a far more rational policy. Namely, the establishment of a free market in labor, so that wage rates can be adjusted to correspond with the

state of the demand for labor and thus make any given monetary demand for labor—any given amount of payroll spending—sufficient to provide full employment. It and the chapter before it also point to the adoption of a 100-percent-reserve gold standard, so that no financial contraction need ever occur and thus no precipitation even of temporary mass unemployment. Such contraction would not occur, because there would be no preceding inflation or credit expansion to set the stage for it by artificially increasing the velocity of circulation of money, promoting the incurrence of debt, and creating money of the kind whose supply can subsequently be decreased by the failure of debtors.

This policy would guarantee full employment in a context of the highest possible productivity of labor. The policies presently pursued by governments are all highly destructive, in serving to reduce the productivity of labor. In addition, for the most part, they are not even capable of actually increasing the overall volume of employment but merely the employment of some at the expense of the employment of others. Unlike those policies, this policy would operate to the benefit of everyone.

The achievement of a free market in labor and a 100-percent-reserve gold standard would mean the elimination of one of modern life's greatest anxieties: the fear of losing one's job and not being able to find another, and thus of being deprived of the ability to support oneself and one's family. With a free market in labor and a 100-percent-reserve gold standard, *there would always be jobs available*. And they would be available without having to wait for any large-scale decline in wage rates. Thus, there would always be a readily available way to earn money. The loss of any given job would cease to be the life-threatening calamity it now so often is and would at most be the source of some temporary unpleasantness.

Appendix to Chapter 13: Inventories and Depressions

An accumulation of business inventories which is excessive in relation to prospective sales volume is almost always associated with the beginning of a depression or recession.¹⁰⁸ The basis of the association is usually explained in the following way: Businessmen find that their inventories are excessive and begin to liquidate them. In order to liquidate them, they attempt to expand their volume of sales while at the same time reducing their volume of production. In reducing their volume of production, they cut back orders with their suppliers and lay off workers. The effect of these cutbacks is to make it more difficult for business firms to expand their sales volume. For the firms that supply other

firms find their orders cut. And the firms that sell to consumers find that many of their customers are unemployed. Thus, inventories continue to be excessive, and further production cutbacks are undertaken, leading to a repetition of the same results.

On the basis of this view, it is easy to conclude that the wealth which the excess inventories constitute is an obstacle to production, employment, and prosperity—that its existence drives economic activity to lower and lower levels, until, by one means or another, it is finally consumed. And, indeed, most people apparently do draw this conclusion. It is generally believed that only the elimination of the wealth constituted by the excess in-

ventories can set the stage for a restoration of production and employment; only then, supposedly, will there be a purpose to be served by maintaining production and employment. This belief is propounded in virtually all financial publications and in practically all economics textbooks. They allege that excess inventories are a cause of depressions and that recovery from a depression begins when inventories have been reduced to the point where additional sales physically require additional production.

The following quotation from a story in the financial section of *The New York Times* some years ago clearly expresses this idea:

He [the Assistant Secretary of Commerce for Economic Affairs] cited, in particular, as a probable cause of continued downturn, the fact that businesses continued to add to their inventories in the fourth quarter. . . . The inventory position of businesses is important because, to the extent that businesses have more inventory on hand than they really need, they cut their production schedules until they have sold the excess.¹⁰⁹

Similarly, a widely-used economics textbook argues that businesses are “ready to start up again,” after they have reached “a position where inventories are short.”¹¹⁰

It should be held in mind that these statements and countless similar statements are made not in reference to the production of particular products, but in reference to economic activity in general. They do not say that the production of this or that particular item will be decreased or increased depending on whether its inventory is excessive or deficient. They claim that the *general level* of economic activity is inversely related to the size of inventories—that the presence of excess inventories is a general economic depressant, and that a shortage of inventories is a general economic stimulant.

Now such ideas have absurd implications. They imply that *the existence of wealth is a cause of poverty* and, further, that *prosperity could be achieved through the destruction of wealth*. These implications are inescapable, for if, in fact, the existence of excess inventories were an obstacle to production and employment, the wealth they represent would be a cause of poverty. And it would follow that production, employment, and prosperity could be restored by burning down warehouses and destroying the excess inventories.

The supporters of the excess-inventory doctrine, of course, are rarely consistent enough to draw such logical inferences from their premises. Instead of recommending arson, they recommend government spending. The government, they urge, should give people money to buy up quantities of goods, thereby reducing inventories and, it is held, restoring the need to produce. Whether they recommend arson or government spending, however, what is essential is that they perceive the physical wealth constituted by excess inventories as an obstacle to pros-

perity and call for its removal.

What I will show is that the existence of excess inventories relative to sales volume, while certainly a cause of unemployment in particular lines of work, is *not* a cause of general unemployment or depressions, even though it is almost always closely associated with these phenomena. I will show that the reason for the *association* of excess inventories with depressions is that both are the effects of the same underlying cause: namely, an inflation of the money supply. I will show that inflation—i.e., an increase in the quantity of money caused by the government—brings about a wasteful accumulation of inventories *at the expense of other, more efficient forms of wealth*, thereby reducing the overall quantity of wealth. When inflation stops or is significantly slowed, these losses are revealed. The existence of the excess inventories themselves, however, then serves to help make good for the losses which have occurred in other forms of wealth.

The connection I will demonstrate between excess inventories and the impoverishment of depressions can be described by the following analogy: Imagine a miraculous kind of typhoon that came and pulled out all the lumber in houses and left it neatly stacked in lumber yards. The existence of this lumber would have two connections to the state of economic well-being. On the one hand, the greater the quantity of such lumber, the more damaging the preceding typhoon must have been. On the other hand, the existence of the lumber would be a means to repair the damage, and if more lumber could be brought into existence through means other than the typhoon, the restoration of prosperity would be so much the easier. This, I will show, is the nature of the excess inventories that exist at the onset of a depression. They are the effect of a process of impoverishment, but are themselves a cause acting in the direction of prosperity. The real problem is not that they are excessive, but, from the standpoint of making up for the damage done, *deficient*. In addition, as part of this demonstration, I will show that the decline in the spending of money that takes place with the onset of a depression is not the result of the existence of excess inventories, but of other factors associated with inflation and its cessation or slowing down. In other words, I will show that all of the adverse or seemingly adverse consequences usually attributed to excess inventories are merely associational and not caused by the inventories, and that the effect of the existence of the inventories themselves is entirely to the good.

Inventories and Capital

The underlying fallacy in the doctrine that excess inventories cause depressions and general unemployment becomes obvious when one considers the situation

of an imaginary Robinson Crusoe on a desert island. If Crusoe is able to salvage a year's supply of canned goods from his ship, he has an excess inventory of food. Does this mean that if he is an industrious person and does not want to spend a year stagnating on his beach, until the need to obtain additional food is forced upon him by the exhaustion of his inventory, he should throw the canned goods back into the ocean? Common sense and economic science must answer no.

The possession of the excess inventory of food does not prevent Crusoe from working. It simply spares him the necessity of directly and immediately producing additional food. During the year in which he does not have to devote his labor to picking berries or killing animals with his bare hands, he can produce other goods, which without the inventory of food he would not have had the time to produce. Above all, he can produce tools, implements, and materials which will enhance his ability to produce food and other goods after his initial inventory is exhausted.

The excess inventory of food is not an obstacle to Crusoe's employment and production. On the contrary, it is the *source* of his employment in the production of other things. It is a fund which supports him while he works and thus makes possible the production of other things. As the inventory of food is consumed, other forms of wealth are produced. Indirectly, by way of supporting his labor, the excess inventory of food is transformed into tools, implements, materials, and supplies of goods that are ready for final consumption, none of which wealth is excessive in any sense.

Were it not for this excess inventory, certainly, Crusoe's production would be curtailed, both in the present and in the future. In the present, he would be limited to the attempt to produce the barest supply of food. And in the future, his production would not have the advantage of the tools, implements, and materials which are made possible by the excess inventory of food. The time which he could devote to employment in the abstract would be no less, but he would have no employment insofar as it contributed to or depended on the use of tools, implements, and materials whose production only the excess inventory of food could make possible.

The underlying fallacy in the doctrine that excess inventories cause depressions is that it does not see production in its full context. It does not see excess inventories as a base for the production of tools, implements, plant and equipment, and other inventories which are not excessive. It does not grasp how one type of wealth can be transformed into another type by means of its consumption serving as the support for the other's production.

The principles pertaining to Crusoe's economy per-

tain equally to the more complicated, monetary economy of today.

An inventory is a source of sales receipts. A firm which possesses an excess inventory possesses to that extent a source of revenue which does not have to be devoted to the reproduction of the inventory. The money gradually coming in from the sale of the excess inventory over time is available to be spent by the firm for other purposes or to be lent to other firms. It can be used to finance construction projects, the purchase of machinery, or the production of inventories of other goods. What is certain is that the money will not be hoarded merely because it is not required to reproduce the same inventory. Not spending to reproduce a particular inventory is not, as is naïvely assumed, not to spend at all.

A canning firm with an excess inventory will reduce its expenditures to produce inventories of canned goods, just as Crusoe with an excess inventory of food will not labor to produce food. But this does not mean that the *overall* expenditures of the canning firm or of those to whom it lends will be reduced, any more than it means Crusoe does not work because he does not work at producing food.

Moreover, it is not a contradiction to argue that firms with excess inventories may employ the revenues those inventories bring in to expand the plant facilities for producing the very goods inventories of which are said to be excessive. It is altogether possible, for example, that an automobile firm might employ the revenues from its excess inventory for the purpose of installing additional facilities for the production of automobiles. For its present inventory is not excessive in the absolute sense that there are not enough potential buyers of cars—at lower prices there would be. It is only excessive in the sense that present costs, using present plant and equipment, are too high to make the rapid sale of the inventory profitable at the lower prices that would be necessary to sell it quickly. If, however, the inventory can be used to finance the installation of lower-cost plant and equipment, it is altogether possible that subsequently the firm's regular production and sales might be profitable at such an expanded volume that what is presently considered to be an excessive inventory in relation to sales, would at that time be considered a deficient inventory.

The *causal* as opposed to the associational relationship between inventories and depressions is not merely different from what is generally believed, it is *the exact opposite*. In a depression and in the period which precipitates a depression, inventories are excessive only in relation to sales volume. As an asset item, however, they are *deficient*. They are deficient in the sense that if they

were sufficiently larger, the mass bankruptcy of business enterprises, which is an outstanding feature of a depression, could not possibly take place. An inventory is an *asset*. No firm has ever or will ever go bankrupt because its assets are too large. Bankruptcies result from assets—from inventories—*not being large enough*.

To the degree that an enterprise possesses a large inventory, it is necessarily in a sounder financial position. Its assets exceed its liabilities by that much more. Its owners are richer. It represents a safer investment for creditors. It itself is more in a position to grant credit to others. To argue that it could go bankrupt because it possessed excessive inventories is to argue that Rockefeller could go bankrupt because he owned too many oil wells.

An inventory is wealth. Whoever possesses an inventory obtains the money he needs by the sale of goods out of his inventory, and, if necessary, can always borrow against the inventory. A rich man is not someone with a great hoard of money, but someone with a large ownership of physical assets, of which inventory is a major form. To be wealthy does not mean to have a vast hoard of paper *dollars* in some strongbox. It means owning a store full of valuable goods, a lot full of automobiles, a warehouse full of merchandise.

By definition, wealthy people do not go bankrupt so long as they continue to be wealthy. And they continue to be wealthy to the degree that they own physical assets such as inventories.

What is true is that an enterprise can be plunged into bankruptcy if it holds an excessive inventory *that is financed by the incurrence of debt*. But then the cause is not the inventory, but the debt. If the firm had a larger inventory and the same debt, it would be less likely to be bankrupted, while if it had a smaller inventory and the same debt, it would more surely be bankrupted.

The possession of excess inventories is not only incompatible with the bankruptcy of those who possess them, but of others, who do not possess them. The existence of excess inventories guarantees a state of genuine credit ease. The owners of such inventories are ready lenders to those seeking capital. Businesses do not go bankrupt when credit is easily obtainable. They go bankrupt when credit is difficult to obtain. And it becomes difficult to obtain when capital, of which inventories are a leading form, is deficient and funds must be retained in the enterprises which earn them in order to maintain current or prospective operations.

In sum, if inventories were truly excessive, there could not possibly be a credit contraction or mass bankruptcies. Those who truly possess excessive inventories do not appear in the market with a desperate need for funds; they more likely appear as lenders rather than as

borrowers. And because—to the degree that their inventories are excessive—they afford strong security on any loans they have taken out, they are not pressed by their creditors; if they are asked to repay their debts, they have the means of doing so. It is firms with an asset-inventory deficiency which have an urgent need for money; it is such firms which are unable to repay their debts and which go bankrupt. But even many of these firms would not go bankrupt, if other firms possessed excess inventories and were therefore in a position to extend them credit.

Rather than calling for the elimination of excess inventories, it would be far more logical to argue that what is needed to end a depression is precisely an *accumulation* of inventories. For it is additional capital that is required, and to whatever extent additional inventories could be brought into being without first entailing a loss of other forms of capital, they would constitute additional capital. A policy of deliberate consumption of inventories, on the other hand, only destroys the means of supporting employment and production and of extending credit. Such a policy can only intensify a depression.

“Excess” Inventories, Malinvestment, and the Deficiency of Inventories

None of these observations is contradicted by anything in anyone's experience. For example, it might be thought that the large inventories held by the automobile industry in the recession of 1974–75 were a cause of that recession. This is not true. The only connection between the inventory of the automobile firms and the recession was that the capital to produce this inventory had been invested at the expense of other employments which could have put it to better use. Had the auto industry not proceeded with the production of this inventory, capital funds would have been available to construct other things, such as power plants, houses, and, perhaps, lower-cost manufacturing facilities for automobiles. Instead, this capital was wasted to a significant degree by having been invested in an inventory of automobiles. But given the malinvestment of capital in producing automobiles, it is far better that the inventory of automobiles existed than that it did not exist. This is so because the sale of cars out of inventory made it possible for much of the malinvested capital to be recovered. Revenues the auto industry took in from the sale of its inventory could be made available for financing these other things, thus helping to rectify the initial mistake.

And if, given the same degree of malinvestment, the inventories of the auto firms had been larger than they were, the severity of the recession would have been less. Imagine, for example, that by some miracle, the auto industry had awakened one morning in 1975 to find

everything else the same except that instead of having an inventory equal to three or four months' sales, it had an inventory twice as large. This would have represented a vast increase in the wealth of the automobile industry and of the whole economy. The auto industry, of course, would have cut back its rate of production still further. It might even have suspended current production altogether. But it would have had the financial means of continuing to pay its workers and suppliers enough to retain their services until such time as normal production resumed, and it would have had the means of infusing substantial sums of capital into all other industries. Home building could have revived, improved manufacturing facilities could have been constructed in a host of industries, more bridges and tunnels could have been built, and so on—all with funds flowing in from the sale of automobiles that did not have to be reproduced. And the suppliers and workers of the auto industry would have participated to a significant degree in the opportunities created by this genuine capital boom. The steel industry, for example, would have turned out more steel for construction and machinery while it turned out less steel for automotive use. And many of the auto industry's workers would have been employed in producing bulldozers, cranes, trucks, locomotives, farm machinery, and the like.

As matters stood, the inventories of the auto industry and all other industries were grossly insufficient to finance all the power plants, pipelines, factories, machines, homes, and so forth, that had been neglected as the result of the malinvestment of capital due to inflation in the years preceding the 1974–75 recession.

Inflation and Credit Expansion as the Cause of Malinvestment in Inventories

Inflation is responsible for the malinvestment of capital in inventory at the expense of other forms of wealth in the following way. As the additional money constituted by inflation comes to be spent and respent, the sales revenues of businesses rise and prices rise. After a while, the continuation of this process comes to be anticipated. Businessmen come to believe that they will be able to sell inventories of goods into a steadily rising demand and at higher prices. Thus, they begin to accumulate inventory. The accumulation of inventory is greatly facilitated—indeed, would probably not be possible otherwise—by the fact that much of the expansion of the money supply enters the economy in the form of new loans. Because this additional money appears on the market as an additional supply of loanable funds, it drives down the rate of interest or prevents the rate of interest from rising to the height it would achieve as the result of inflation alone. This means that it becomes possible to

borrow money at relatively low rates of interest and use it to finance the wasteful accumulation of inventories.¹¹¹

Such conditions characterized the American economy in the 1970s. Interest rates were below the rate at which prices were rising. Thus, it was possible to make money merely by stockpiling inventory.

This stockpiling of inventory is very aptly characterized by the analogy I used earlier of a typhoon that pulled the lumber out of houses and stacked it in lumber yards. The inventories, of course, do not result from the literal disassembly of already produced goods. They do result, however, at the expense of the production of other goods. Thus, piles of inventory accumulate at the expense of factories, machines, houses, and so forth, that could have been produced, if the means of producing them had not been diverted to producing inventories instead. The net result is as though these goods were destroyed and their remains thrown into piles of inventory. Inflation and credit expansion are indeed a kind of typhoon.

Why “Excess” Inventories and Monetary Contraction Are Associated

When inflation is stopped or significantly slowed down, the uneconomic nature of the investments in inventory is revealed. First, interest rates rise, because the depressing effect on the rate of interest of inflation-financed loans is removed. And then the rise in sales revenues and prices begins to abate, because the quantity of money no longer increases or increases much less rapidly. Thus, the profit is taken out of the wasteful inventory investments, and, unless the inflation is quickly resumed, these inventories must be sold on the market at a loss.

The cessation or slowing down of inflation thus reveals widespread losses of capital in the form of unproductive inventory investments. In addition to revealing losses, the cessation or slowing down of inflation increases the need of business firms to hold cash. This effect explains why the liquidation of inventories in depressions is accompanied by “cash hoarding” rather than equivalent spending in support of other forms of capital accumulation.

During inflation, and so long as inflation is expected to continue rapidly enough, businessmen are induced to operate with unduly low levels of cash in relation to the financial size of their operations. Cash holdings fall as a percentage of assets, liabilities, revenues, and expenditures. Among the reasons is the fact that inflation in the form of credit expansion leads businessmen to believe that credit will be easily available when they need it. At the same time, they come to expect to be able to sell their inventories easily and profitably. On the basis of such convictions, they come to regard their existing levels of

cash as unnecessarily large and as better placed in income-earning assets. Thus, cash holdings come to be drawn down. Since the cash does not disappear from the economic system, but is merely transferred in exchange for something to someone else, who will also tend to be less conservative in his attitude toward cash holdings, what happens is an expansion in the volume of spending, lending, borrowing, and trading of all kinds, in relation to the quantity of money. When inflation stops or is significantly slowed down, however, the basis of the low cash holdings is removed, because credit turns out not to be available or to be available only at a much greater cost and with much greater difficulty than had been expected. And inventories turn out not to be as readily and profitably saleable as believed. Thus, when inflation stops or is significantly slowed down, business enterprises must begin to rebuild their cash holdings.

This necessary rebuilding of cash holdings is why there is a reduction in the general rate of spending in the economy and why the liquidation of excess inventories in the aftermath of an inflation, does not provide an equivalent financial support for other business activities. Namely, practically all firms are trying to retain a larger proportion of the funds they take in, in the form of cash. The sellers of the excess inventories use part of their proceeds to rebuild their own cash positions; and of the funds that these sellers do make available to others, as loans, for example, a portion is retained by the recipients in the form of replenished cash holdings. And it is the

same with the liquid funds realized in any other way. Thus, the rate of spending slows down. It cannot be stressed too strongly that it is not the excess inventories that are the cause of the reduced volume of spending. On the contrary, both the excess inventories and the reduced volume of spending are the consequence of the distortions created by the preceding inflation and credit expansion.

What has been shown is that the relationship between excess inventories and depressions is one of association, not causation. Excess inventories and depressions are both the result of a process of inflation—specifically, of an inflation that enters the economy in the form of loans granted out of newly created money, that is, of credit expansion. The excess inventories represent impoverishment only in their origin—insofar as they are the result of the diversion of capital from other, more important employments. In their consequence, however, the effect of the existence of these inventories is to help make good for the losses entailed in their accumulation. And these losses would be all the more easily made good, if, with the same degree of malinvestment, the excess inventories were greater. In this sense, inventories in a depression are deficient, not excessive.

The existence of assets can never be the cause of bankruptcies. The existence of wealth can never be the cause of poverty. The possession of excess inventories that is associated with depressions does not contradict these principles in the slightest.

Notes

1. Concerning the fundamental problem of economic life, see above, pp. 42–51 and 54–61.
2. Most of what follows in this part derives from my article “Production Versus Consumption,” *Freeman* 14, no. 10 (October 1964), pp. 3–12; reprinted as a pamphlet (Laguna Hills, Calif.: The Jefferson School of Philosophy, Economics, and Psychology, 1991).
3. In reality, Ricardo and especially James Mill propounded it with far greater clarity and consistency than Say. In my judgment, the law should actually be called James Mill’s Law.
4. See above, p. 112.
5. For a brilliant analysis of this error and of its consequences, see Henry Hazlitt, *Economics in One Lesson*, new ed. (New Rochelle, N. Y.: Arlington House Publishers, 1979). 34. *Ibid.*, p. 306.

35. For elaboration of this point, see below, pp. 817–818. See also below, pp. 569–580.

36. For another instance of the fallacy of composition in connection with consumptionism, see above, pp. 543–544.

37. See below, pp. 762–767.

38. Not surprisingly, Prof. Samuelson has missed few opportunities to belittle the gold standard over the course of the fourteen editions of his book.

39. David Ricardo, *Principles of Political Economy and Taxation*, 3d ed. (London, 1821), chap. 21; reprinted as vol. 1 of *The Works and Correspondence of David Ricardo*, ed. Piero Sraffa (Cambridge: Cambridge University Press, 1962), pp. 291–292. Italics supplied.

40. All of these propositions, of course, presuppose a normal context, that is, a context in which business firms have not been

led into a state of illiquidity by a preceding inflation or credit expansion and now realize their need to rebuild liquidity. In such conditions, monetary demand falls. Its stabilization and renewed increase requires a fall in wage rates and prices sufficient to accommodate the fall in the velocity of circulation of money that is the necessary accompaniment of the rebuilding of liquidity. The problem of adjustment can be compounded by a fall in the quantity of money, in which case a further reduction in wage rates and prices is necessary. For further discussion of these points, see below, pp. 580–589 and 938–940.

41. James Mill, *Commerce Defended* (London, 1808), chap. 6; reprinted in *Selected Economic Writings of James Mill*, ed. Donald Winch (Chicago: The University of Chicago Press, 1966), p. 135.

42. I choose the fraction one-third for the new price of potatoes simply because it is the first fraction with one as the numerator that is less than a half, and is thus probably the easiest fraction to work with.

43. It should be realized that it is no objection to Say's Law to question the assumption that the “other goods” no longer offered for the given good are equivalently exchanged against themselves. To whatever extent they might not be, the corollary effect would be that the supply of such other goods brought to market would be equivalently less. Thus, to whatever extent the rise in aggregate demand turned out to be less than the increase in the supply of the given good, it would be less only to the extent of the accompanying decrease in the supply of other goods. The proposition would remain that the increase in aggregate demand was precisely equal to the increase in aggregate supply, whatever it was.

44. I elaborate on this point below, on pp. 568–569.

45. See above, pp. 53–54.

46. Concerning mass unemployment, see below, pp. 580–582. Concerning the determination of real wages, see below, pp. 618–622.

47. See below, p. 725, for confirmation of this statement.

48. For such an analysis, see below, pp. 719–859, which provide a full elaboration of the theory of aggregate profit and interest. See also below, pp. 622–642, which explain the vital role of the demand for capital goods in the process of capital accumulation and raising the productivity of labor.

49. Even though there is no demand for capital goods in the conditions of full vertical integration, there could still be capital—in the form of capitalized wage payments. For example, if a sum such as \$1 million is paid to wage earners to construct a durable asset, or to produce inventory, that \$1 million is capitalized in the asset accounts of the firm that pays the wages.

50. See below, p. 576, for an explanation of why broad-based increases in production under a commodity money system actually tend to be accompanied by a *higher* rather than a lower average rate of profit.

51. See above, pp. 543–544.

52. For a comprehensive explanation of how improvements in the productivity of labor are the essential cause of rising real wages, see below, pp. 613–663.

53. See above, p. 518.

54. Closely related to this last are cases in which an increase in the demand for money results from the demand for money having first been artificially reduced in expectation of an *accel-*

eration in the rate of increase in the quantity of money. In cases of this kind, the demand for money increases if the expected acceleration in the rate of increase in the quantity of money does not take place.

55. See above, pp. 519–526.

56. The need for accelerated depreciation of business plant and equipment as the result of more rapid economic progress should not be taken to imply any tendency toward a substantially smaller accumulated value of net plant and equipment in the conditions of an invariable money, still less, any reduction in the degree of capital intensiveness in the economic system. On the contrary, it is accompanied by an increase in the degree of capital intensiveness. For an explanation of the reasons why, see below, pp. 786–787.

57. See below, pp. 589–590. See also Ludwig von Mises, *Human Action*, 3d ed. rev. (Chicago: Henry Regnery Co., 1966), pp. 568–569.

58. From that point on, the stock of housing in any given year would consist of the new housing production of that year and of 49 prior years, with each succeeding year's housing production being 5 percent greater than that of the year before. In the next year, each of the 50 terms representing a year's housing production would increase by 5 percent, with the result that the total stock of housing would increase by 5 percent.

59. Today's depressed housing market in places such as California should not be ascribed to an inelastic demand for housing. Rather it is the result of a fall in the demand for housing following decades in which credit expansion artificially encouraged housing construction and then experienced major interruption. The problems of the housing market in California are also greatly compounded by the fact that the state has been rendered economically uncompetitive by the policies of its government, which have included higher taxes and more regulation than competing states, as well as numerous measures deliberately designed to discourage economic progress.

60. Ultimately, the supply of new housing will stand to the total stock of housing not in the ratio of 1:50, but in the substantially

higher ratio of $1.05^{50} \div \sum_{n=1}^{50} 1.05^n$.

61. On the role of saving in the demand for expensive durable goods, see below, p. 694. On the relationship between saving and economic progress, see below, pp. 622–629.

62. See below, pp. 663–664.

63. See above, pp. 513–514 and 519–526. As we will see, there can also be reductions in the aggregate demand for labor in conjunction with increases in the aggregate demand for capital goods. But such reductions are relatively slow and modest in the overall economic system, and when they occur are the basis of a more rapidly growing ability to produce, including a growing ability to produce or import the precious metals, and thus of an expanding quantity of money and growing demand for labor. On this subject, see below, pp. 639–641.

64. See below, pp. 762–767.

65. Concerning the role of saving in the demand for labor, see above, pp. 478–480, and below, pp. 632–634, 683–685, 694–696, and 725–736. Finally, on the relationship between the demand for labor and the demand for capital goods and why decreases in the demand for labor caused by increases in the

demand for capital goods are not against the interests of the average wage earner, see below, pp. 639–641.

66. See above, the last reference in the preceding note.

67. On this subject, see below, p. 590.

68. See above, Chapters 6–8.

69. We have already seen how it is to the advantage of poor wage earners, above, on pp. 382–384.

70. The legitimacy of generalizing about the rate of profit from the results of the assumption of the full vertical integration of business was explained earlier in this chapter, on p. 570, when the assumption was first introduced. At that time, it was also explained how capital can exist even in the absence of a demand for capital goods. See above, the preceding page, n. 49.

71. See below, pp. 864–878, for a detailed exposition of Keynes's theories. Following that exposition, I show that the effect of a fall in wage rates necessary to achieve full employment is actually to increase the rate of profit rather than merely leave it unchanged. See below, pp. 879–884, especially pp. 883–884.

72. For an explanation of why taxes levied on profits or interest are a burden to wage earners, and the magnitude of that burden, see above, pp. 306–310. See also below, pp. 826–829.

73. This is the view of von Mises, for example. See *Human Action*, pp. 776–777.

74. As I will show in the next chapter, a rising productivity of labor is the only possible cause of a sustained, significant rise in average real wages, which, other things being equal, vary in direct proportion to the average productivity of labor. See below, pp. 618–622 and 646–653.

75. See above, pp. 358–360. The greater division of labor contributes to the rise in the productivity of labor not only directly, but also indirectly, insofar as it brings about a greater production of capital goods. On this subject, see below, pp. 634–636, where it is shown how anything that serves to increase production in general, increases the production and accumulation of capital goods.

76. On this last point, see the preceding note.

77. Unemployment tends to be more heavily concentrated in the blue-collar ranks, probably because, by and large, such workers tend to be easier to replace than the administrative-type workers.

78. In order for any major problem of greater difficulty of paying debt to be caused by a fall in the aggregate demand for labor, the fall in the aggregate demand for labor must itself be major. As we are already in a position to know, the explanation of such a fall is a general financial contraction brought on by a decrease in the quantity of money and/or increase in the demand for money for holding, which last is itself caused by a cessation or slowdown in the rate of increase in the quantity of money. On this subject, see below, the next two notes.

79. On the nature of inflation, see above, pp. 219–220 and 503–506, and below, pp. 895–907. On the role of fiduciary media and credit expansion in the precipitation of monetary contractions, see above, pp. 511–517 and 519–526. See also below, pp. 938–941.

80. See above, pp. 519–526.

81. See above, pp. 520–522, and below, pp. 938–940.

82. Also present here is the phenomenon known as "credit crunches," which also are the result of credit expansion. On this aspect, see below, pp. 939–940.

83. See above, pp. 513–514.

84. See above, *ibid.*

85. On the subject of the Phillips curve, see Samuelson and Nordhaus, *Economics*, pp. 328–335.

86. See below, the next section, especially pp. 591–592.

87. See Murray N. Rothbard, *America's Great Depression* (Princeton, N. J.: D. Van Nostrand & Co., 1963), pp. 187–190, 236–239.

88. It is appropriate here to recall the words of Adam Smith, who wrote, "I have never known much good done by those who affected to trade for the public good." (See Adam Smith, *The Wealth of Nations* [London, 1776], bk. 4, chap. 2; reprint of Cannan ed. [Chicago: University of Chicago Press, 2 vols. in 1, 1976], 2:478.)

89. See U.S. Department of Commerce, Bureau of Economic Analysis, *The National Income and Product Accounts of the United States, 1929–1976 Statistical Tables* (Washington, D. C.: U.S. Government Printing Office, 1981), pp. 238 and 253. These pages provide the data on the basis of which the calculations in the text have been made.

90. See Rothbard, *America's Great Depression*, p. 183.

91. On the significance of the qualification concerning compensating advantage, see above, pp. 576–578.

92. See *National Income and Product Accounts of the United States, 1929–1976 Statistical Tables*, p. 1, for the data used to make these calculations.

93. As should be evident from this discussion, there are determinants of aggregate profit other than the difference between consumption expenditure and wage payments, notably, net investment. For elaboration, see below, pp. 744–750. See also pp. 700–706, which deal with the nature of net investment.

94. On the subject of springs to profitability, see below, pp. 778–787, especially p. 784.

95. The restoration of investment spending, when wage rates fall to their equilibrium level, is guaranteed by the operation of

the aforementioned springs to profitability.

96. See above, pp. 511–517 and 519–526.

97. On these points, see below, pp. 938–940. See also below, pp. 935–936.

98. On the subject of malinvestment, see below, pp. 935–936. See also below, pp. 597–598.

99. See above, pp. 515–516.

100. See above, p. 524.

101. See *National Income and Product Accounts of the United States, 1929–1976 Statistical Tables*, pp. 238 and 253 for the data underlying these calculations. The calculations use the data for private industries in line 3 of the tables.

102. Data for the number of workers reported as openly unemployed are from U.S. Department of Commerce, Bureau of the Census, *Historical Statistics of the United States Colonial Times to 1970* (Washington, D. C.: U.S. Government Printing Office, 1975), p. 126. Data for the number of workers employed in the various government work-relief programs are from the *National Income and Product Accounts of the United States, 1929–1976 Statistical Tables* p. 253.

103. See above, pp. 258–262, especially p. 262.

104. See p. 262.

105. See above, pp. 287–288.

106. See *National Income and Product Accounts of the United States, 1929–1976 Statistical Tables*, pp. 3, 23, and 254. My calculations of federal government spending include "government transfer payments to persons."

107. See below, pp. 622–629 and 632–634.

CHAPTER 14

THE PRODUCTIVITY THEORY OF WAGES

PART A

THE MARXIAN EXPLOITATION THEORY

1. The Influence of the Exploitation Theory

The Marxian exploitation theory has been and continues to be among the most influential economic doctrines in the world. Despite the global collapse of socialism, it continues to be the prevailing theory of wages. Its truth in the explanation of the determination of wage rates is taken for granted both by the overwhelming majority of intellectuals and by the great mass of ordinary citizens in all countries of the world. It is for this reason that I find it necessary to begin my discussion of wage rates with an account of this theory.

According to the exploitation theory, capitalism is a system of virtual slavery, serving the narrow interests of a comparative handful of “exploiters”—the businessmen and capitalists—who, driven by insatiable greed and power-lust, exist as parasites upon the labor of the masses. This view of capitalism has not been the least bit shaken by the steady rise in the standard of living of the average person that has taken place in the capitalist countries since the beginning of the Industrial Revolution. The rise in the standard of living is not attributed to capitalism, but precisely to the *infringements* that have been made upon capitalism. Thus, people attribute economic progress to labor unions and social legislation, and to what

they consider to be improved personal ethics on the part of employers. By the same token, they tremble at the thought of unions not existing, of a society without minimum-wage laws, maximum-hours legislation, and child-labor laws—at the thought of a society in which no legal obstacles stood in the way of employers pursuing their self-interest. In the absence of such legislation, people believe, wage rates would return to the minimum-subsistence level; women and children would labor once more in the mines; and the hours of work would be as long and as hard as it is possible for human beings to bear—all for the benefit of the businessmen and capitalists, precisely as Marx maintained.

As I have indicated, the exploitation theory has been and continues to be a guiding force in the thoughts and actions not only of the various Communist and socialist parties around the world, but also in those of the great majority of people who regard themselves as anticommunists and antisocialists. It is believed to be correct by almost everyone, not as a description of present-day conditions, to be sure, but as a description of the workings of *laissez-faire* capitalism—of capitalism free of all government intervention into the economic system, of capitalism as displayed in its essential nature in the nineteenth century.

Thus, the exploitation theory is almost universally accepted as the basis for the interpretation of modern economic history. Even the great majority of anticommunists and antisocialists believe that economic conditions in the nineteenth century were bad for the average person because of the unrestrained greed of the capitalists. By the

same token, the subsequent improvement in economic conditions is almost universally believed to be the result of government intervention that limits the operation of that greed.

The belief in the essential correctness of the exploitation theory as applied to laissez-faire capitalism underlies the advocacy of the so-called mixed economy and the welfare state—of virtually the whole economic program of the present-day “liberals.” Among the measures enacted and maintained in force as the result of its influence are not only maximum-hours, minimum-wage, prounion, and child-labor legislation, but also progressive income and inheritance taxes and social-welfare spending, such as that for public housing, public education, social security, and socialized medicine. It is believed that none of these measures is at the expense of the workers, but only of the capitalists. Their cost, it is believed, comes exclusively at the expense of the capitalists’ profits—from “surplus-value.” From the point of view of the workers, it is thought, the measures represent nothing but a source of gains: less work, higher wages, and more housing, education, income security, medical care, and so forth.

In effect, these measures are perceived merely as giving back to the workers some of the wealth allegedly exploited from them by the capitalists. Indeed, the validity of the exploitation theory is so taken for granted that “liberal” politicians routinely campaign on the assumption that no possible basis can exist for opposing their allegedly humanitarian projects except membership in the class of the “rich”—that is, of the capitalist exploiters—or else some utterly perverse desire to prevent the great mass of people from being benefitted at no cost to themselves.

Thus, the influence of the exploitation theory is to be found not in any support it may provide for a Communist revolution, but in the perception it offers of the allegedly evil nature of capitalism and the need to control that allegedly evil nature, which perception is held by the overwhelming majority of people, especially by the overwhelming majority of today’s intellectuals. In this essential respect, the influence of the exploitation theory is as great as ever. Indeed, the exploitation theory is the leading manifestation of the prescientific, demonological worldview that I described in Chapter 1 as continuing to be prevalent in economics.¹ The alleged good and evil arbitrary powers that are supposed to rule the economic world according to that view are, first and foremost, the businessmen and capitalists of the Marxian exploitation theory, who, of course, are the allegedly evil powers, and the government of the “liberals” and the socialists, which is the allegedly good power.

The remaining sections of this part present an exposi-

tion of the substantive content of the exploitation theory, the conceptual framework of the exploitation theory having already been presented and refuted in Chapter 11.² That substantive content is the Marxian version of the labor theory of value and the Marxian version of the iron law of wages, both of which represent profound distortions of the classical economists’ ideas on these subjects, as a comparison with the relevant portions of Chapter 11 will clearly confirm.³ Because Chapter 11 has already presented in great detail a mutually exclusive version of the labor theory of value, it will not be necessary in this chapter to present any further critique of this aspect of the exploitation theory. The mere presentation of the Marxian version of the labor theory of value will be enough to refute it, in the light of the material previously presented in Chapter 11. However, the same cannot be said for the iron law of wages, and thus Part B of this chapter incorporates a critique of the Marxian version of the iron law of wages, mainly in the form of the positive exposition of the mutually exclusive theory of wages that I call the productivity theory of wages and after which I have titled both Part B and the present chapter as a whole.

While the productivity theory of wages can be interpreted as a flat-out alternative to the ideas of the classical economists on the subject of wages, I believe that it is actually the theory of wages that is consistent with the essential core of classical economics. For example, it is very closely related to Say’s Law, in that just as Say’s Law explains real demand as determined by production and supply, so the productivity theory of wages explains real wages as also determined by production and supply—specifically, by the production and supply of goods relative to the supply of labor.⁴ It is also closely related to the classical economists’ ideas on saving and capital accumulation and to their doctrine of the wages-fund theory.⁵ In addition, of course, as I have already indicated, it is consistent both with Ricardo’s doctrine on profits and with his views on the labor theory of value, both of which I have shown to be in actual opposition to the exploitation theory.⁶

2. Marx’s Distortions of the Labor Theory of Value

Marx twists the labor theory of value into a form in which Smith and certainly Ricardo would not have supported it. He proceeds as though the quantity of labor required to produce a good were the *sole, exclusive* determinant of its price, ignoring all the repeated statements by Ricardo in particular to the contrary.⁷ He seems never to have heard of categories of goods whose prices are determined by supply and demand, nor of the time factor, the rate of profit, and differences in wage rates as

factors influencing prices. He writes:

A use-value, or useful article, therefore, has value only because human labour in the abstract has been embodied or materialized in it. How, then, is the magnitude of this value to be measured? Plainly, by the quantity of the value creating substance, the labour, contained in the article. The quantity of labour, however, is measured by its duration, and labour-time in its turn finds its standard in weeks, days, and hours.⁸

In answer to the objection that his theory implies that commodities should be more valuable the more idle and unskillful the workers are who produce them, Marx states that he is speaking of “socially necessary” labor-time. “The labour-time that is socially necessary,” he explains, “is that required to produce an article under the normal conditions of production, and with the average degree of skill and intensity prevalent at the time.”⁹

The phenomenon that is actually referred to with these words is market *competition*. But competition and its effects are quickly forgotten. For competition is responsible for the fact that, in the same market at the same time, equal quantities of products of the same type sell for the same price, irrespective of the very different amounts of labor that may have been expended to produce them. In the very next paragraph, in full contradiction of what he has just said about socially necessary labor time, Marx declares:

Commodities, therefore, in which equal quantities of labour are embodied, or which can be produced in the same time, have the same value. The value of one commodity is to the value of any other, as the labour-time necessary for the production of the one is to that necessary for the production of the other. “As values, all commodities are only definite masses of congealed labour-time.”¹⁰

The problem created for Marx’s version of the labor theory of value by the existence of skilled labor is disposed of with equal sleight of hand, a few pages later. This problem is the fact that the products of a given amount of skilled labor tend to be worth more than the products of the same number of hours of unskilled labor—a circumstance which represents a direct contradiction of the proposition that the value of all commodities is in proportion simply and only to the relative quantities of labor required to produce them. Marx writes: “Skilled labour counts only as simple labour intensified, or rather, as multiplied simple labour, a given quantity of skilled labour being considered equal to a greater quantity of simple labour. . . . For simplicity’s sake we shall henceforth account every kind of labour to be unskilled, simple labour; by this we do no more than save ourselves the trouble of making the reduction.”¹¹

Thus, with these difficulties out of the way, Marx feels free to develop his own peculiar, absolutist version of the labor theory of value—a version which recognizes noth-

ing but the quantity of labor as the determinant of exchange ratios and prices. A few samples of his virtual obsession with the notion of “congealed labour” follow:

The equation, 20 yards of linen = 1 coat, or 20 yards of linen are worth one coat, implies that the same quantity of value-substance (congealed labour) is embodied in both; that the two commodities have each cost the same amount of labour or the same quantity of labour-time.¹²

Therefore, 10 lbs. of tea = 40 lbs. of coffee. In other words, there is contained in 1 lb. of coffee only one-fourth as much substance of value—labour—as is contained in 1 lb. of tea.¹³

In this sense, every commodity is a symbol, since, in so far as it is value, it is only the material envelope of the human labour spent upon it.¹⁴

Thus, in Marx’s view, the exchange value of commodities is determined by their congealed labor content. Every commodity is perceived as containing so much labor that has entered into its production. The value of every commodity relative to the value of every other commodity, i.e., their mutual exchange ratio, is then seen as nothing but a ratio of their respective congealed labor contents. The price of every commodity is seen as nothing but the ratio of the labor required to produce a unit of it to the labor required to produce a unit of gold. If, for example, an article sells for ten dollars, it can only be, according to Marx, because it takes ten times the labor to produce a unit of it as it does to produce the quantity of gold defined as one dollar.

Marx, in other words, presents what I call an absolutist version of the labor theory of value—a version which, totally unlike that of the classical economists, holds that the quantity of labor required to produce something is always the determinant of its value and is the sole and exclusive determinant of its value. Marx’s “congealed labour” can only be understood as some kind of alleged pulsating sweat-content that is immanent in commodities, and that allegedly gives off some kind of charged field, so to speak, whose interaction with the similarly charged fields of other commodities supposedly determines exchange ratios and prices, and does so in proportion to the respective pulsating sweat-contents—that is, to the respective “congelations” of “labour.”

Implications for Value Added and Income Formation

Marx’s absolutist version of the labor theory of value provides a remarkably simple explanation of the determination of “surplus-value”—i.e., of the extent of the alleged deduction of profits from wages that the exploitation theory fallaciously claims. (Marx, of course, mistakenly believes that surplus-value—profit—comes into existence only with the appearance of businessmen and capitalists, under “capitalistic circulation.”¹⁵)

His absolutist version of the labor theory of value implies that the total of the value added at any stage in production, and thus the total of the income earned in that stage of production—that is, the sum of profits and wages together—must be due to the performance of fresh labor at that stage of production. This is because any product that is produced contains all of the labor that went into producing the materials required for its production. It also contains an appropriate share of the labor that entered into producing the machines and factory buildings that were used in its production. (On this last point, Marx says, for example, “Suppose a machine to be worth 1000 pounds, and to wear out in 1000 days. Then one thousandth part of the value of the machine is daily transferred to the day’s product.”¹⁶) If the product is to be worth more than the nonhuman means of production—the materials and plant and equipment—used up or otherwise productively consumed in producing it, then it must, according to Marx’s absolutist version of the labor theory of value, be the product of a larger number of hours of labor than entered into those means of production. This is possible only to the extent that fresh labor is applied in transforming the materials, with the aid of the machinery and factory buildings, into the product. In Marx’s own words:

We have seen that the [nonhuman] means of production transfer value to the new product, so far only as during the labour process they lose value in the shape of their old use-value. The maximum loss of value that they can suffer in the process, is plainly limited by the amount of the original value with which they came into the process, or in other words, by the labour-time necessary for their production. Therefore the means of production can never add more value to the product than they themselves possess independently of the process in which they assist. However useful a given kind of raw material, or a machine, or other means of production may be, though it may cost 150 pounds or, say, 500 days’ labour, yet it cannot, under any circumstances, add to the value of the product more than 150 pounds. Its value is determined not by the labour-process into which it enters as a means of production, but by that out of which it has issued as a product. In the labour-process it only serves as a mere use-value, a thing with useful properties, and could not, therefore, transfer any value to the product, unless it possessed such value previously.¹⁷

But, we are told:

It is otherwise with the subjective factor of the labour-process, with labour-power in action. While the labourer, by virtue of his labour being of a specialised kind that has a special object, preserves and transfers to the product the value of the means of production, he at the same time, by the mere act of working, creates each instant an additional or new value. . . . The substitution of one value for another, is here effected by the creation of a new value.¹⁸

In accordance with this view, Marx introduces his

distinction between “constant capital” and “variable capital.” The constant capital, representing the portion of capital invested in materials, machinery, and factory buildings, allegedly conveys to the product only the value it itself represents. It is in no way value creating. In this sense it is “constant.” The variable capital, however, that is, the portion of the capital invested in the payment of wages—in the purchase of “labour-power”—is value creating. In this sense it is “variable.” In Marx’s words:

That part of capital then, which is represented by the means of production, by the raw material, auxiliary material and the instruments of labour, does not, in the process of production, undergo any quantitative alteration of value. I therefore call it the constant part of capital, or, more shortly, *constant capital*.

On the other hand, that part of capital, represented by labour-power, does, in the process of production, undergo an alteration of value. . . . This part of capital is continually being transformed from a constant into a variable magnitude. I therefore call it the variable part of capital, or shortly, *variable capital*.¹⁹

The “variable capital,” then, is variable in the sense that in employing fresh labor, it alone makes it possible for the product to contain more hours of labor than the materials and other constituents of the constant capital. And thus the value of the product can be greater than the value of the nonhuman means of production used up or otherwise productively consumed in producing it.

Now to the extent that the value of a product exceeds the value of the nonhuman means of production, income exists in the form of profits plus wages. Profit, of course, is the excess of the value of the product over the value of all of the means of production required to produce it, including the fresh labor applied at the current stage of production. It is the excess of the value of the product over the total costs of production. The value merely of the nonhuman means of production used up or otherwise productively consumed in order to produce a product is equal to all the costs of production *but wages*. Thus, when this amount is subtracted from the value of the product, the difference is profits *plus wages*. That is, sales – (cost – wages) = profits + wages.²⁰ For example, if the value of a product is \$100 and the costs of producing it are \$80, the profit earned is \$20. If, of the \$80 of total costs, the costs on account of capital goods are \$45, while the costs on account of labor are \$35, then the difference between the value of the product and the value of the capital goods alone is equal to \$100 – \$45, which is \$55. This \$55 in turn is equal to the sum of the profit of \$20 plus the wage cost of \$35. That the difference between the value of the product and the value of the capital goods alone is equal to the sum of the profit plus the wages can be seen directly, by recognizing that \$100 – \$45 is equal to \$100

– (\$80 – \$35), which, of course, equals the \$20 of profit plus the \$35 of wages.

In just this way, fresh labor is perceived as adding to the value of the nonhuman means of production consumed in producing the product the sum of wages and profits together. The sum of the wages and the profits together earned at any given stage of production is held to be in proportion to the fresh labor added at that stage.

It should be realized that, according to Marx's view, if there were a fully automated factory, requiring the performance of virtually no fresh labor to transform materials into a product, the value of the product could not exceed the value of the materials plus the depreciation on the machinery and factory. Similarly, according to Marx's view, there is no way of explaining the well-known fact that older wine or whiskey has a higher value than younger wine or whiskey, even though no additional labor is performed in the aging process.

3. Marx's Version of the Iron Law of Wages

Now, according to Marx, what determines the division of the value added—allegedly all by the performance of fresh labor—between wages and profits is a further application of his absolutist version of the labor theory of value. This time Marx applies his absolutist version of the labor theory of value to the determination of the value of labor itself, and, in so doing, provides his own peculiar version of the so-called iron law of wages. The value of labor, or “labour-power,” as Marx calls it, is allegedly determined *by the quantity of labor required to produce labor!* The meaning of this proposition is explained by Marx in the following words:

The value of labour-power is determined, as in the case of every other commodity, by the labour-time necessary for the production, and consequently also the reproduction, of this special article. So far as it has value, it represents no more than a definite quantity of the average labour of society incorporated in it. Labour-power exists only as a capacity, or power of the living individual. Its production consequently presupposes his existence. Given the individual, the production of labour-power consists in his reproduction of himself or his maintenance. For his maintenance he requires a given quantity of the means of subsistence. Therefore the labour-time requisite for the production of labour-power reduces itself to that necessary for the production of those means of subsistence; in other words, the value of labour-power is the value of the means of subsistence necessary for the maintenance of the labourer.²¹

In elaboration, Marx writes:

The value of labour-power resolves itself into the value of a definite quantity of means of subsistence. It therefore varies with the value of these means or with the quantity of labour requisite for their production.

Some of the means of subsistence, such as food and fuel, are consumed daily, and a fresh supply must be provided daily. Others such as clothes and furniture last for longer periods and require to be replaced only at longer intervals. One article must be bought or paid for daily, another weekly, another quarterly, and so on. But in whatever way the sum total of these outlays may be spread over the year, they must be covered by the average income, taking one day with another. If the total of the commodities required daily for the production of labour-power = A, and those required weekly = B, and those required quarterly = C, and so on, the daily average of these commodities = $(365A+52B+4C+\&c.)$. Suppose that in this mass of com-

365

modities requisite for the average day there are embodied 6 hours of social labour, then there is incorporated daily in labour power half a day's average social labour, in other words, half a day's labour is requisite for the daily production of labour-power. This quantity of labour forms the value of a day's labour-power or the value of the labour-power daily reproduced. If half a day's average social labour is incorporated in three shillings, then three shillings is the price corresponding to the value of a day's labour-power. If its owner [viz., the wage earner] therefore offers it for sale at three shillings a day, its selling price is equal to its value, and according to our supposition, our friend Moneybags, who is intent upon converting his three shillings into capital, pays this value.²²

It should be observed that when Marx and his followers denounce capitalism for treating labor “like a commodity,” what they really mean, as these passages make plain, is that they believe that under capitalism the value of labor is determined in the same way as the value of *products*—i.e., by the quantity of labor required to produce it. It should also be observed where Marx stands literarily and intellectually in resorting to the use of such expressions as “our friend Moneybags” in referring to the capitalist employer.

Marx repeats some of the qualifications of Ricardo about the meaning of “subsistence.” He says:

. . . the number and extent of his [the wage earner's] so-called necessary wants, as also the modes of satisfying them, are themselves the product of historical development, and depend therefore to a great extent on the degree of civilisation of a country, more particularly on the conditions under which, and consequently on the habits and degree of comfort in which, the class of free labourers has been formed. In contradistinction therefore to the case of other commodities, there enters into the determination of the value of labour-power a historical and moral element. Nevertheless, in a given country, at a given period, the average quantity of the means of subsistence necessary for the labourer is practically known.²³

Nevertheless, Marx's version of the iron law of wages fundamentally differs from that of the classical economists. This is because Marx assumes that wages are somehow directly determined by “subsistence,” totally

apart from any connection to population growth and the operation of the law of diminishing returns. (According to the classical economists, of course, what created the alleged tendency of wages toward subsistence was precisely population growth and the ensuing operation of the law of diminishing returns.²⁴) Wages are supposedly put at subsistence directly—by the arbitrary will of the capitalists. And, at bottom, despite the passage quoted, when Marx speaks of subsistence, he usually means it in a strict, biological sense. In his view, if employers can get away with it, they will pay wages sufficient to cover only the cost of the commodities *vitaly necessary to the worker's survival*—and not even that. He declares:

Capital cares nothing for the length of life of labour-power. All that concerns it is simply and solely the maximum of labour-power, that can be rendered fluent in a given working day. It attains this end by shortening the extent of the labourer's life, as a greedy farmer snatches increased produce from the soil by robbing it of its fertility.²⁵

In *The Communist Manifesto*, Marx declares:

The average price of wage-labor is the minimum wage, i.e., that quantum of the means of subsistence, which is absolutely requisite to keep the laborer in bare existence as a laborer. What, therefore, the wage-laborer appropriates by means of his labor, merely suffices to prolong and reproduce a bare existence.²⁶

He even states that “The constant tendency of capital is to force the cost of labour back towards zero.”²⁷

In reading Marx, it is difficult to avoid reaching the conclusion that, in his view, if the capitalists could operate without restraint of any kind, there would be a section in the financial pages of the newspapers that does not presently appear—namely, a listing of the prices of such wage earners' necessities as potatoes, bread, and loin-cloths, and the rentals of cardboard shanties and mud huts. The capitalists, supposedly, would then periodically adjust wages to conform with the changes in these prices.

The Rate of Exploitation Formula

Marx's essential idea that fresh labor adds all value and yet is paid in accordance only with the labor required to “produce” it—that is, produce its necessities—gives rise to his formula for the expression of the degree of exploitation of the worker by the capitalist. I quote him at length:

We have seen that the labourer, during one portion of the labour-process, produces only the value of his labour-power, that is, the value of his means of subsistence. Now since his work forms part of a system, based on the social division of labour, he does not directly produce the actual necessities which he himself consumes; he produces instead a particular commodity, yarn for example, whose value is equal to the value of those necessities or of the

money with which they can be bought. The portion of his day's labour devoted to this purpose, will be greater or less, in proportion to the value of the necessities that he daily requires on average, or, what amounts to the same thing, in proportion to the labour-time required on average to produce them. If the value of those necessities represents on an average the expenditure of six hours' labour, the workman must on an average work for six hours to produce that value. If instead of working for the capitalist, he worked independently on his own account, he would, other things being equal, still be obliged to labour for the same number of hours, in order to produce the value of his labour-power and thereby to gain the means of subsistence necessary for his conservation or continued reproduction [viz., for his continued ability to work]. But as we have seen, during that portion of his day's labour in which he produces the value of his labour-power, say three shillings, he produces only an equivalent for the value of his labour-power already advanced by the capitalist; the new value created only replaces the variable capital advanced [viz., the wages paid]. It is owing to this fact, that the production of the new value of three shillings takes the semblance of a mere reproduction. That portion of the working day, then, during which this reproduction takes place, I call “*necessary*” labour-time, and the labour expended during that time I call “*necessary*” labour. Necessary as regards the labourer, because independent of the particular social form of his labour; necessary, as regards capital, and the world of capitalists, because on the continued existence of the labourer depends their existence also.

During the second period of the labour-process, that in which his labour is no longer necessary labour, the workman, it is true, labours, expends labour-power; but his labour, being no longer necessary labour, he creates no value for himself. He creates surplus-value which, for the capitalist, has all the charms of a creation out of nothing. This portion of the working day, I name surplus labour-time, and to the labour expended during that time, I give the name surplus labour. It is every bit as important, for a correct understanding of surplus-value, to conceive it as a mere congelation of surplus-labour-time, as nothing but materialised surplus-labour, as it is, for a proper comprehension of value, to conceive it as a mere congelation of so many hours of labour, as nothing but materialised labour. The essential difference between the various economic forms of society, between, for instance, a society based on slave labour, and one based on wage labour, lies only in the mode in which this surplus-labour is in each case extracted from the actual producer, the labourer.

Since, on the one hand, the values of the variable capital and of the labour-power purchased by that capital are equal, and the value of this labour-power determines the necessary portion of the working day; and since, on the other hand, the surplus-value is determined by the surplus portion of the working day, it follows that surplus-value bears the same ratio to variable capital, that surplus-labour does to necessary labour, or in other words, the rate of surplus-value $\frac{s}{v} = \frac{\text{surplus labor}}{\text{necessary labor}}$. Both ratios, $\frac{s}{v}$ and $\frac{\text{surplus labor}}{\text{necessary labor}}$

express the same thing in different ways; in the one case by reference to materialised, incorporated labour, in the other by reference to living, fluent labour.

The rate of surplus-value is therefore an exact expression for the degree of exploitation of labour-power by capital, or of the labourer by the capitalist.²⁸

Marx's doctrine is thus actually the essence of simplicity. Fresh labor adds the entire amount by which the value of a product exceeds the value of the nonhuman means of production consumed in producing the product. But that labor is not paid in accordance with the number of hours for which it works, but in accordance with the smaller number of hours of labor required to produce the necessities that give the worker the capacity to work. To the extent that the workers work more hours than corresponds to the hours required to produce their necessities, they perform surplus labor, which is the foundation of surplus-value.

To express the idea even more simply, the consumption of necessities produced by only six hours of labor gives a worker the ability to perform twelve hours of labor. The capitalist is thus allegedly enabled to buy a working day of twelve hours at a wage corresponding to the six hours of labor required to produce the necessities that make possible the twelve hours of labor. The capitalist is therefore able to add twelve hours of labor to the value contained in the nonhuman means of production that must be consumed in order to produce his product, and he obtains that labor for a wage corresponding to only six hours of labor. In other words, he allegedly obtains twelve hours of labor, and the value added by twelve hours of labor, for a wage corresponding only to six hours of labor. This is the alleged source of his profit and of all other forms of "surplus-value." It is allegedly unpaid labor time. In Marx's own words:

Let us examine the matter more closely. The value of a day's labour amounts to 3 shillings, because on our assumption half a day's labour is embodied in that quantity of labour-power, i.e., because the means of subsistence that are daily required for the production of labour-power, cost half a day's labour. But the past labour that is embodied in the labour-power, and the living labour that it can call into action; the daily cost of maintaining it, and its daily expenditure in work, are two totally different things. The former determines the exchange-value of the labour-power, the latter is its use-value. The fact that half a day's labour is necessary to keep the labourer alive during 24 hours, does not in any way prevent him from working a whole day. Therefore, the value of labour-power, and the value which that labour power creates in the labour-process, are two entirely different magnitudes; and this difference of the two values was what the capitalist had in view, when he was purchasing the labour-power. The useful qualities that labour-power possesses, and by virtue of which it makes yarn or boots, were to him nothing more than a *conditio sine qua*

non; for in order to create value, labour must be expended in a useful manner. What really influenced him was the specific use-value which this commodity possesses of being *a source not only of value, but of more value than it has itself.*²⁹

The following example makes the substance of Marx's entire system clear. (It should be noted that this example is virtually identical with the one extensively employed by Marx himself, except for the use of dollars rather than English shillings, and for the assumption that a unit of money represents just one hour of "congealed labor-time" rather than two such hours.³⁰)

Assume as a universal principle that for every hour of labor "congealed" in a product, there corresponds \$1 of product value. (This would imply, according to Marx, that on a gold standard, 1 hour of labor was required to produce the quantity of gold defined as \$1.) Assume in particular that the production of a certain quantity of cotton yarn begins with a quantity of raw cotton that is itself the product of 40 hours of labor. The money value of this raw cotton is, accordingly, \$40. Assume further that the machinery by means of which, and the factory building in which, the yarn is produced lose a portion of their useful life in the processing of this particular batch of raw cotton which represents an additional 8 hours of labor. (In order to better understand this last assumption, we might assume that the machinery and factory building have required 8 million hours of labor to construct, and have a useful life such that they can contribute to the processing of a million batches of raw cotton such as the one they presently process. In that case the machinery and factory building contribute 8 hours of labor to the production of each of one million batches of yarn.) The monetary value of the contribution of the machinery and factory building to the batch of yarn is, accordingly, \$8.

Thus, in this example, we have a "constant capital" used up representing 48 hours of congealed labor in all, and therefore \$48 of monetary value. These 48 hours of labor congealed in the constant capital now pass over into the product, the cotton yarn. The cotton yarn is the product of all the labor that has entered into the constant capital used up to produce it and, in addition, is the product of the fresh, additional labor that is applied within the cotton mill itself. We assume with Marx that the quantity of this fresh, additional labor is 12 hours. On these assumptions, we end up with a quantity of cotton yarn that is the product of 60 hours of labor in toto—48 hours contributed by way of the constant capital used up to produce it and 12 hours more contributed by the fresh, additional labor that is employed in the cotton mill to process the raw cotton with the aid of the plant and equipment constituted by the mill. The monetary value of the resulting cotton yarn is, of course, \$60.

The difference between the monetary value of the cotton yarn and the monetary value of the constant capital used up to produce the yarn is \$12, precisely corresponding to the 12 hours of fresh, additional labor performed. The \$12 represent the sum of all incomes earned at this stage of the process of production. They are the sum of the profits (and all other forms of “surplus-value”) and the wages together. For they equal the \$60 value of the product minus the \$48 of costs of nonhuman means of production, that is, the costs other than wages. And thus, by the formula that $sales - (cost - wages) = profits + wages$, \$60 of sales minus \$48 of costs other than wages equals \$12 of profits plus wages.

And now we come to see just how, according to Marx, profits and all other forms of “surplus-value” are deducted from the value supposedly added by the labor of the wage earners. The alleged “secret of profit making,” to use Marx’s expression, is that for the 12 hours of fresh, additional labor, and thus for the addition of \$12 of monetary value to the constant capital that is used up, the capitalist pays a wage that corresponds not to the time the worker works, *but to the time required to produce the necessities the worker requires in order to be able to work*—the necessities he requires in order to be able to deliver his “labour-power.” If the worker can perform 12 hours of labor by means of consuming necessities produced in only 6 hours, then the capitalist buys his 12 hours of labor for a wage of only \$6. In this way allegedly, he obtains a product containing 60 hours of labor and worth \$60, at a cost of only \$54. He incurs a cost of \$48 on account of constant capital that is used up and a further cost of only \$6 for the performance of the 12 hours of labor. The “secret” is that he allegedly receives 6 hours of labor—the labor the worker performs in excess of what is equivalent to providing for his subsistence, i.e., the so-called surplus labor—that he, the capitalist, does not pay for. What he allegedly pays for is only the labor equivalent to what is required to produce the wage earner’s necessities, i.e., the so-called necessary labor. In this way, says Marx,

Every condition of the problem is satisfied, while the laws that regulate the exchange of commodities have been in no way violated. Equivalent has been exchanged for equivalent. For the capitalist as buyer paid for each commodity, for the cotton, the spindle and the labour-power, its full value. He then did what is done by every purchaser of commodities; he consumed their use-value. . . .

By turning his money into commodities that serve as the material elements of a new product, and as factors in the labour-process, by incorporating living labour with their dead substance, the capitalist at the same time converts value, i.e., past, materialized, and dead labour into capital, into value big with value, a live monster that is fruitful and multiplies.³¹

4. Implications of the Exploitation Theory

It should be clear from the preceding discussion that the Marxists are deadly serious when they speak of “wage slavery” and describe all of history as a “class struggle” in which today’s wage earners are the counterpart of the slaves and serfs of previous ages and in which today’s businessmen and capitalists are the counterpart of the slave owners and feudal aristocrats of former times.³² Marx’s theory of “surplus-value” explains profit and the other nonwage incomes as the result of precisely the same facts that make possible the gains of a slave owner. The source of a slave owner’s gain is the fact that a slave can perform more labor than is required to provide for his own subsistence. The excess goes to the benefit of the slave owner. Precisely that is held to be the source of the capitalist’s profit and of every other form of “surplus-value.”

The exploitation theory also implies that the workers are men without a country and “have nothing to lose but their chains,” as *The Communist Manifesto* declares.³³ According to the exploitation theory, all economic progress simply passes the workers by. The effect of economic progress is to make available new and better goods and to reduce the prices of existing goods. But, according to the exploitation theory, the effect of reductions in the prices of goods purchased by the wage earners is a corresponding reduction in wages and increase in the portion of the worker’s labor time appropriated for the creation of surplus-value. In the words of Marx:

The value of commodities is in inverse ratio to the productiveness of labour. And so, too, is the value of labour-power, because it depends on the value of commodities. . . . [S]urplus-value is, on the contrary, directly proportional to that productiveness. It rises with rising and falls with falling productiveness. The value of money being assumed to be constant, an average social working day of 12 hours always produces the same new value, six shillings, no matter how this sum may be apportioned between surplus-value and wages. But if, in consequence of increased productiveness, the value of the necessaries of life fall, and the value of a day’s labour be thereby reduced from five shillings to three, the surplus-value increases from one shilling to three. Ten hours were necessary for the reproduction of the value of the labour-power; now only six are required. Four hours have been set free, and can be annexed to the domain of surplus-labour. Hence there is immanent in capital an inclination and constant tendency, to heighten the productiveness of labour, in order to cheapen commodities, and by such cheapening to cheapen the labourer himself.³⁴

Thus, according to Marx, the wage earners are deprived of the ability to buy any larger quantity of the goods whose prices fall and, by the same token, of the ability to set aside funds for the purchase of goods they

did not previously purchase. Thus, all economic progress allegedly operates exclusively to the benefit of the “exploiters.”

The exploitation theory implies not only that all economic progress passes the workers by, but, still worse, that the workers actually fall into a deepening state of impoverishment. In the words of *The Communist Manifesto*:

Hitherto, every form of society has been based, as we have already seen, on the antagonism of oppressing and oppressed classes. But in order to oppress a class, certain conditions must be assured to it under which it can, at least, continue its slavish existence. The serf, in the period of serfdom, raised himself to membership in the commune, just as the petty bourgeois, under the yoke of feudal absolutism, managed to develop into a bourgeois.

The modern laborer, on the contrary, instead of rising with the progress of industry, sinks deeper and deeper below the conditions of existence of his own class. He becomes a pauper and pauperism develops more rapidly than population and wealth. And here it becomes evident that the bourgeoisie is unfit any longer to be the ruling class in society, and to impose its conditions of existence upon society as an over-riding law. It is unfit to rule, because it is incompetent to assure an existence to its slave within his slavery, because it cannot help letting him sink into such a state that it has to feed him, instead of being fed by him.³⁵

The theoretical basis for the doctrine of progressive impoverishment is a combination of two alleged circumstances that are supposedly unique to capitalism: an allegedly limitless greed for surplus-value on the part of capitalists, which supposedly arises from the nature of production for the sake of monetary gain, and an alleged tendency toward a declining rate of profit, which latter supposedly requires a rising rate of exploitation in order to limit the decline. In connection with the first of these circumstances, Marx writes:

As capitalist, he is only capital personified. His soul is the soul of capital. But capital has one single life impulse, the tendency to create value and surplus-value, to make its constant factor, the means of production, absorb the greatest possible amount of surplus-labour.

Capital is dead labour, that vampire-like, only lives by sucking living labour, and lives the more, the more labour it sucks. The time during which the labourer works is the time during which the capitalist consumes the labour-power he has purchased of him.³⁶

It is, however, clear that in any given economic formation of society, where not the exchange value but the use-value of the product predominates, surplus labour will be limited by a given set of wants which may be greater or less, and that here no boundless thirst for surplus-labour arises from the nature of production itself. Hence in antiquity overwork becomes horrible only when the object is to obtain exchange value in its specific independent money form; in the production of gold and silver.³⁷

The doctrine of a falling rate of profit is implied in the exploitation theory on Marx’s assumption that economic progress and capital accumulation are accompanied by a growth in so-called constant capital relative to “variable” capital. In Marx’s own words:

Suppose 100 pounds are the wages of 100 labourers for, say, one week. If these labourers perform equal amounts of necessary and surplus labour, if they work daily as many hours for themselves, i.e., for the reproduction of their wage, as they do for the capitalist, i.e., for the production of surplus-value, then the value of their total product = 200 pounds, and the surplus-value they produce would amount to 100 pounds. The rate of surplus-value, $\frac{s}{v}$, would = 100 percent. But, as we have seen, this rate of surplus-value would nonetheless express itself in very different rates of profit, depending on the different volumes of constant capital c and consequently of the total capital C , because the rate of profit = $\frac{s}{C}$. The rate of surplus-value is 100 percent:

If $c = 50$, and $v = 100$, then $p' = \frac{100}{150} = 66\frac{2}{3}\%$;

“ $c = 100$, and $v = 100$, then $p' = \frac{100}{200} = 50\%$;

“ $c = 200$, and $v = 100$, then $p' = \frac{100}{300} = 33\frac{1}{3}\%$;

“ $c = 300$, and $v = 100$, then $p' = \frac{100}{400} = 25\%$;

“ $c = 400$, and $v = 100$, then $p' = \frac{100}{500} = 20\%$.

This is how the same rate of surplus-value would express itself under the same degree of labour exploitation in a falling rate of profit, because the material growth of the constant capital implies also a growth—albeit not in the same proportion—in its value, and consequently in that of the total capital.³⁸

Not surprisingly, in his chapter on counteracting influences concerning the tendency toward a falling rate of profit, Marx provides “Increasing Intensity of Exploitation” and “Depression of Wages Below The Value of Labour-Power” as section headings 1 and 2.³⁹ He declares: “The tendency of the rate of profit to fall is bound up with a tendency of the rate of surplus-value to rise, hence with a tendency for the rate of labour exploitation to rise.”⁴⁰ For, as Marx’s example above indicates, a rise in the rate of “surplus-value” can correspondingly offset the alleged negative effects on the rate of profit of a rise in “constant capital” relative to “variable capital.”

In Marx’s view, the inherent greed of the capitalists, and the tendency of the rate of profit otherwise to fall, leads the capitalists to seek to extend the working day to the maximum possible limit, as a principal means of raising the rate of “surplus-value.” In effect, the capital-

ists see the workers lolling about after work in pubs or amusing themselves on playing fields, expending energy that the food provided by the capitalists has made possible. Instead of allowing that energy to be wasted in such idleness, the capitalists will allegedly capture it in the factories, in the production of commodities, where it can add to the magnitude of “surplus-value.” They allegedly accomplish this by reducing hourly wages, thereby compelling the workers to work longer hours to earn subsistence. The result is a corresponding rise in the amount and rate of “surplus-value,” and an accompanying offset to the fall in the rate of profit. If, for example, the working day can be extended to eighteen hours from twelve hours, while the worker still requires necessities produced in only six hours, then the rate of surplus-value is increased from 100 percent to 200 percent. For $\frac{s}{v} = \frac{\text{surplus labor}}{\text{variable capital}} = \frac{18 - 6}{6} = 200$ percent. Thus, the rate of profit can allegedly be doubled, or at least maintained in conditions in which it would otherwise have been cut in half.

Marx describes the “greed for surplus-labour” in the following words:

“What is a working day? What is the length of time during which capital may consume the labour-power whose daily value it buys? How far may the working day be extended beyond the working time necessary for the reproduction of labour-power itself?” It has been seen that to these questions capital replies: the working day contains the full 24 hours with the deduction of the few hours of repose without which labour-power absolutely refuses its services again. Hence it is self-evident that the labourer is nothing else, his whole life through, than labour-power, that therefore all his disposable time is by nature and law labour-time, to be devoted to the self-expansion of capital. Time for education, for intellectual development, for the fulfilling of social functions and for social intercourse, for the free-play of his bodily and mental activity, even the rest time of Sunday (and that in a country of Sabbatarians!)—moonshine! But in its blind unrestrainable passion, its were-wolf hunger for surplus-labour, capital oversteps not only the moral, but even the merely physical maximum bounds of the working day. It usurps the time for growth, development, and healthy maintenance of the body. It steals the time required for the consumption of fresh air and sunlight. It higgles over a meal-time, incorporating it where possible with the process of production itself, so that food is given to the labourer as to a mere means of production, as coal is supplied to the boiler, grease and oil to the machinery. It reduces the sound sleep needed for the restoration, reparation, refreshment of the bodily powers to just so many hours of torpor as the revival of an organism, absolutely exhausted, renders essential. It is not the normal maintenance of the labour-power which is to determine the limits of the working day; it is the greatest possible daily expenditure of labour-power, no matter how diseased, com-

pulsory, and painful it may be, which is to determine the limits of the labourers’ period of repose.⁴¹

The greed for “surplus-value,” claims Marx, leads the capitalists to appropriate the labor of women and children in exactly the same way as, he alleges, they appropriate the additional hours of labor of the adult males. Namely, they reduce wage rates and thereby make it necessary for a wage earner’s entire family to perform labor in order to earn enough for the family to obtain subsistence. In this way, once again, the expenditure of energy made possible by the food the capitalists enable the workers to buy is allegedly captured in the production of commodities and thus in the generation of “surplus-value.” Now, in exchange for a wage enabling the worker to buy the products of the same 6 hours of “necessary labor,” or perhaps just a little more, the capitalist allegedly obtains the equivalent perhaps of 48 hours of total labor, as the labor of the adult male is joined by the full-time labor of his wife and children. And thus the rate of surplus-value can rise to 700 percent. For $\frac{s}{v} = \frac{\text{surplus labor}}{\text{variable capital}} = \frac{48 - 6}{6} = 700\%$.

Marx describes this alleged phenomenon in the following passages of *Das Kapital*, in which he blames machinery for making such exploitation possible:

In so far as machinery dispenses with muscular power, it becomes a means of employing labourers of slight muscular strength, and those whose bodily development is incomplete, but whose limbs are all the more supple. The labour of women and children was, therefore, the first thing sought for by capitalists who used machinery. That mighty substitute for labour and labourers was forthwith changed into a means for increasing the number of wage-labourers by enrolling, under the direct sway of capital, every member of the workman’s family, without distinction of age or sex. Compulsory work for the capitalist usurped the place, not only of the children’s play, but also of free labour at home within moderate limits for the support of the family.

The value of labour-power was determined, not only by the labour-time necessary to maintain the individual adult laborer, but also by that necessary to maintain his family. Machinery, by throwing every member of that family on to the labour market, spreads the value of the man’s labour-power over his whole family. It thus depreciates his labour-power. To purchase the labour-power of a family of four workers may, perhaps, cost more than it formerly did to purchase the labour-power of the head of the family, but, in return, four days’ labour takes the place of one, and their price falls in proportion to the excess of the surplus-labour of four over the surplus-labour of one. In order that the family may live, four people must now, not only labour, but expend surplus-labour for the capitalist. Thus, we see, that machinery, while augmenting the human material that forms the principal object of capital’s exploiting power, at the same time raises the degree of exploitation.⁴²

No absurdity escapes Marx in applying his doctrine that the capitalists arbitrarily pay the worker a wage conforming to the labor time needed to produce his minimum subsistence. Thus, according to Marx, still a further means of increasing the rate of “surplus-value” is “the intensification of labor”—what the labor unions nowadays describe as a “speedup.” The intensification of labor represents the performance of more labor in a given time, and supposedly increases surplus-value both by reducing the labor time required to produce the worker’s necessities and by representing the equivalent of a lengthening of the hours of work as well.⁴³ It allegedly becomes of particular importance after the enactment of laws limiting the length of the working day.⁴⁴

And, beyond this, yet still another alleged method of raising the rate of “surplus-value,” according to Marx, is a cheapening of the worker’s diet.⁴⁵ If the workers could be forced to substitute potatoes or rice for more expensive food, the so-called necessary labor time would be reduced and “surplus-labor-time” correspondingly increased.

This then is the exploitation theory—a doctrine so contorted in its development and so grotesque and absurd in its implications that it deserves to evoke laughter in the very act of being expounded. Nevertheless, instead of being greeted with laughter, the doctrine has been taken with the utmost seriousness and, as I have shown, stands as the intellectual foundation of the whole economic and social program of twentieth century “liberalism.” Above all, the mentalities that have posed as liberal “intellectuals” in the last century and a quarter—that is, as serious thinkers—have taken the validity of the theory absolutely for granted and as the starting point of their economic and social programs.

According to them, if not prevented by government intervention, the capitalists would, indeed, set wage rates at the point of minimum subsistence and the hours of work at the maximum possible limit, in order to maximize their profits. But government intervention, they believe, especially in the form of prounion legislation, can serve to decree higher wage rates, and all that occurs is that “surplus-labor-time” and “surplus-value” are reduced, thereby equivalently benefitting the wage earners at the expense of the capitalist exploiters’ profits. In exactly the same way, the “liberal intellectuals” believe that the government’s and the unions’ decree of shorter hours also serves merely to reduce “surplus-labor-time” and “surplus-value,” again allegedly benefitting the wage earners at the expense of the capitalist exploiters’ profits. And, of course, identically the same analysis is present in their arguments for child labor legislation and laws compelling improvements in working conditions.

With the exploitation theory as their foundation, the

“liberal intellectuals” contribution to the life of their times has been to set about busying themselves both with the critique of the capitalist society in which they have lived, and with the concoction of all manner of schemes and programs for overcoming the various evils that the exploitation theory in its flights of fancy absurdly and maliciously attributes to capitalism. They have bent art and literature, history and journalism, even philosophy and science, as well as politics, law, and government to conform with the exploitation theory and its ludicrous implications.

When the absurdities of the exploitation theory are fully understood, as they ought to be by the end of this chapter, it will be clear that never in all of human history has a greater bunch of pompous ignoramuses with pretensions to knowledge behaved more destructively and self-destructively—made themselves more a spectacle of downright fools meriting the utter contempt of all mankind—than have the “liberal intellectuals” of the last four or five generations. Their lack of genuine liberalism will be seen to be surpassed only by their lack of genuine intellect.

In the next part of this chapter, my first order of business will be to thoroughly overturn the Marxian version of the iron law of wages—that is, the belief, so central to the exploitation theory, that wages are determined by the arbitrary power of businessmen and capitalists, or at least would be if not for the existence of such measures as prounion legislation and minimum-wage and maximum-hours laws. I will then explain how real wages—the goods and services that a worker’s money wages can actually buy—are determined by the productivity of labor, that is, by the output per unit of labor prevailing in the economic system. The remainder of the part will constitute a refutation of all aspects of the exploitation theory which may thus far have escaped direct criticism. As I have indicated previously, the refutation will be accomplished primarily simply by means of developing the implications and underlying foundations of the fact that real wages are determined by the productivity of labor.

PART B

THE PRODUCTIVITY THEORY OF WAGES

1. The Irrelevance of Worker Need and Employer Greed in the Determination of Wages

The Marxian version of the iron law of wages—that is, the doctrine of the alleged arbitrary power of employ-

ers over wages—appears plausible because there are two obvious facts that it relies on, facts which do not actually support it, but which appear to support it. These facts can be described as “worker need” and “employer greed.” The average worker must work in order to live, and he must find work fairly quickly, because his savings cannot sustain him for long. And if necessary—if he had no alternative—he would be willing to work for as little as minimum physical subsistence. At the same time, self-interest makes employers, like any other buyers, prefer to pay less rather than more—to pay lower wages rather than higher wages. People put these two facts together and conclude that if employers were free, wages would be driven down by the force of the employers’ self-interest—as though by a giant plunger pushing down in an empty cylinder—and that no resistance to the fall in wages would be encountered until the point of minimum subsistence was reached. At that point, it is held, workers would refuse to work because starvation without the strain of labor would be preferable to starvation with the strain of labor.

What must be realized is that while it is true that workers would be willing to work for minimum subsistence if necessary, and that self-interest makes employers prefer to pay less rather than more, both of these facts are *irrelevant* to the wages the workers actually have to accept in the labor market.

Let us start with “worker need.” To understand why a worker’s willingness to work for subsistence if necessary is irrelevant to the wages he actually has to work for, consider the analogous case of the owner of a late-model car who decides to accept a job offer, and to live, in the heart of New York City. If this car owner cannot afford several hundred dollars a month to pay the cost of keeping his car in a garage, and if he cannot devote several prime working hours every week to driving around, hunting for places to park his car on the street, he will be willing, if he can find no better offer, to give his car away for free—indeed, to pay someone to come and take it off his hands. Yet the fact that he is willing to do this is absolutely irrelevant to the price he actually must accept for his car. That price is determined on the basis of the utility and scarcity of used cars—by the demand for and supply of such cars. Indeed, so long as the number of used cars offered for sale remained the same, and the demand for used cars remained the same, it would not matter even if every seller of such a car were willing to give his car away for free, or willing even to pay to have it taken off his hands. None of them would have to accept a zero or negative price or any price that is significantly different from the price he presently can receive.

This point is illustrated in terms of the simple supply and demand diagram presented in Figure 14–1. On the

vertical axis, I depict the price of used cars, designated by P . On the horizontal axis, I depict the quantity of used cars, designated by Q , that sellers are prepared to sell and the buyers to buy at any given price. The willingness of sellers to sell some definite, given quantity of used cars at any price from zero on up (or, indeed, from less than zero by the cost of having the cars taken off their hands) is depicted by a vertical line drawn through that quantity. The vertical line SS denotes the fact that sellers are willing to sell the specific quantity A of used cars at any price from something less than zero on up to as much as they can get for their cars. The fact that they are willing to sell for zero or a negative price has nothing whatever to do with the actual price they receive, which in this case is the very positive price P_1 . The actual price they receive in a case of this kind is determined by the limitation of the supply of used cars, together with the demand for used cars. In Figure 14–1, it is determined at point E , which represents the intersection of the vertical supply line with the demand curve. The price that corresponds to that juncture of supply and demand is P_1 . The fact that the sellers are all willing if necessary to accept a price less than P_1 is, as I say, simply irrelevant to the price they actually must accept. The price the sellers receive in a case of this kind is not determined by the terms on which they are willing to sell. Rather, *it is determined by the competition of the buyers for the limited supply offered for sale.* (This, of course, is the kind of case Böhm-Bawerk had in mind when he declared that “price is actually limited and determined by the valuations on the part of the buyers exclusively.”⁴⁶)

Essentially the same diagram, Figure 14–2, depicts the case of labor. Instead of showing price on the vertical axis, I show wages, designated by W . Instead of the supply line being vertical to the point of the sellers being willing to pay to have their good taken off their hands, I assume that no supply whatever is offered below the point of “minimum subsistence,” M . This is depicted by a horizontal line drawn from M and parallel to the horizontal axis. Thus, the supply curve in this case has a horizontal portion at “minimum subsistence” before becoming vertical. These are the only differences between Figures 14–1 and 14–2.

Figure 14–2 makes clear that the fact that the workers are willing to work for as little as minimum subsistence is no more relevant to the wages they actually have to accept than was the fact in the previous example that the sellers of used cars were willing to give them away for free or pay to have them taken off their hands. For even though the workers are willing to work for as little as minimum subsistence, the wage they actually obtain in the conditions of the market is the incomparably higher wage W_1 , which is shown by the intersection—once

Figure 14-1

Determination of Price by the Competition of the Buyers

again at point E —of the demand for labor with the limited supply of labor denoted by point A on the horizontal axis. Exactly like the value of used cars, or anything else that exists in a given, limited supply, *the value of labor is determined on a foundation of its utility and scarcity, by demand and supply—more specifically, by the competition of buyers for the limited supply—not by any form of cost of production, least of all by any “cost of production of labor.”*⁴⁷

It also quickly becomes clear that “employer greed” is fully as irrelevant to the determination of wage rates as “worker need.” This becomes apparent as soon as the case of the art auction is recalled that I presented in Chapter 6 in order to demonstrate the actual self-interest of buyers.⁴⁸ There I assumed that there are two people at an art auction, both of whom want the same painting. One of these people, let us now call him Mr. Smith, is willing and able to bid as high as \$2,000 for the painting. The other, let us now call him Mr. Jones, is willing and able to go no higher than \$1,000.

Of course, Mr. Smith does not want to spend \$2,000 for the painting. This figure is merely the limit of how high he will go if he has to. He would much prefer to obtain the painting for only \$200, or better still, for only \$20, or, best of all, for nothing at all. What we must recall here is precisely how low a bid Mr. Smith’s rational self-interest allows him to persist in. Would it, for exam-

Figure 14-2

Determination of Wages by the Competition of Employers

ple, actually be to Mr. Smith’s self-interest to persist in a bid of only \$20, or \$200?

It should be obvious that the answer to this question is decidedly no! This is because if Mr. Smith persists in such a low bid, the effect will be that he loses the painting to Mr. Jones, who is willing and able to bid more than \$20 and more than \$200. In fact, in the conditions of this case, Mr. Smith must lose the painting to the higher bidding of Mr. Jones, if he persists in bidding any sum under \$1,000! If Mr. Smith is to obtain the painting, the conditions of the case require him to bid more than \$1,000, because that is the sum required to exceed the maximum potential bid of Mr. Jones.

This case contains the fundamental principle that names the actual self-interest of buyers. That principle is that a buyer rationally desires to pay not the lowest price he can imagine, but *the lowest price that is simultaneously too high for any other potential buyer of the good, who would otherwise obtain the good in his place.*

This identical principle, of course, applies to the determination of wage rates, as I also indicated in Chapter 6.⁴⁹ The only difference between the labor market and the auction of a painting is the number of units involved. Instead of one painting with two potential buyers for it, there are many millions of workers who must sell their services, together with potential employers of all those workers and of untold millions more workers. This is

because just as in the example of the art auction, the essential fact that is present in the labor market is that the potential quantity demanded exceeds the supply available. The potential quantity of labor demanded always far exceeds the quantity of labor that the workers are able, let alone willing, to perform.

For labor, it should be recalled, is scarce. It is the most fundamentally useful and scarce thing in the economic system: virtually everything else that is useful is its product and is limited in supply only by virtue of our lack of ability or willingness to expend more labor to produce a larger quantity of it. (This, of course, includes raw materials, which can always be produced in larger quantity by devoting more labor to the more intensive exploitation of land and mineral deposits that are already used in production, or by devoting labor to the exploitation of land and mineral deposits not presently exploited.⁵⁰) As I have shown, for all practical purposes there is no limit to our need and desire for goods or, therefore, for the performance of the labor required to produce them. In having, for example, a need and desire to be able to spend incomes five or ten times the incomes we presently spend, we have an implicit need and desire for the performance of five or ten times the labor we presently perform, for that is what would be required in the present state of technology and the productivity of labor to supply us with such increases in the supply of goods. Moreover, almost all of us would welcome the full-time personal services of at least several other people. Thus, on both grounds labor is scarce, for the maximum amount of labor available to satisfy the needs and desires of the average member of the economic system can never exceed the labor of just one person, and, indeed, in actual practice, falls far short of that amount because of the existence of large numbers of dependents.⁵¹

The consequence of the scarcity of labor is that *wage rates in a free market can fall no lower than corresponds to the point of full employment*. At that point the scarcity of labor is felt, and any further fall in wage rates would be against the self-interests of employers because then a labor *shortage* would ensue. Thus, if somehow wage rates did fall below the point corresponding to full employment, it would be to the self-interest of employers to bid them back up again.

These facts can be shown in the same supply and demand diagram I used to show the irrelevance to wage determination of workers being willing to work for subsistence. Thus, Figure 14-3 shows that if wage rates were below their market equilibrium of W_1 , which takes place at the point of full employment, denoted by E —if, for example, they were at the lower level of W_2 —a labor shortage would exist. The quantity of labor demanded at the wage rate of W_2 is B . But the quantity of labor

available—whose employment constitutes full employment—is the smaller amount A . Thus, at the lower wage, the quantity of labor demanded exceeds the supply available by the horizontal distance AB .

The shortage exists because the lower wage of W_2 enables employers to afford labor who would not have been able to afford it at the wage of W_1 , or it enables employers who would have been able to afford some labor at the wage of W_1 to now afford a larger quantity of labor. To whatever extent such employers employ labor that they otherwise could not have employed, that much less labor remains to be employed by other employers, who are willing and able to pay the higher wage of W_1 .

For the sake of simplicity, we can assume that at the artificially low wage of W_2 the entire quantity AB of labor is employed by employers who otherwise could not have afforded to employ that labor. (Of course, under the conditions of a shortage, it is a random matter who actually ends up as the employer. But this is inconsequential in the present context. All that is essential to the argument is that any part of the quantity AB of labor end up in the hands of employers who otherwise could not have afforded it.) The effect of this is to leave an equivalently reduced quantity of labor available for those employers who could have afforded the market wage of W_1 . The labor available to those employers is reduced by AC , which is precisely equal to AB . This is the inescapable result of the existence of a given quantity of labor

and some of it being taken off the market by some employers at the expense of other employers. What the one set gains, the other must lose. Thus, because the wage is W_2 rather than W_1 , the employers who could have afforded the market wage of W_1 and obtained the full quantity of labor A are now able to employ only the smaller quantity of labor C , because labor has been taken off the market by employers who depend on the artificially low wage of W_2 .

The employers who could have afforded the market wage of W_1 are in identically the same position as the bidder at the art auction who is about to see the painting he wants go to another bidder not able or willing to pay as much. The way to think of the situation is that there are two groups of bidders for quantity AB of labor: those willing and able to pay the market wage of W_1 , or an even higher wage—one as high as W_3 —and those willing and able to pay only a wage that is below W_1 —a wage that must be as low as W_2 . In Figure 14–3, the position of these two groups is indicated by two zones on the demand curve: an upper zone HE and a lower zone EL . The wage of W_1 is required for the employers in the upper zone to be able to outbid the employers in the lower zone.⁵²

The question is: Is it to the rational self-interest of the employers willing and able to pay a wage of W_1 , or higher, to lose the labor they want to other employers not able or willing to pay a wage as high as W_1 ? The obvious answer is no. And the consequence is that if, somehow, the wage were to fall below W_1 , the self-interest of employers who are willing and able to pay W_1 or more, and who stood to lose some of their workers if they did not do so, would lead them to bid wage rates back up to W_1 . The rational self-interest of employers, like the rational self-interest of any other buyers, does not lead them to pay the lowest wage (price) they can imagine, but the lowest wage that is *simultaneously too high for other potential employers of the same labor who are not able or willing to pay as much and who would otherwise be enabled to employ that labor in their place*.

The principle that it is against the self-interest of employers to allow wage rates to fall to the point of creating a labor shortage is illustrated by the conditions which prevail when the government imposes such a shortage by virtue of a policy of price and wage controls. In such conditions, employers actually conspire with the wage earners to evade the controls and to raise wage rates. They do so by such means as awarding artificial promotions, which allow them to pay higher wages within the framework of the wage controls.

The payment of higher wages in the face of a labor shortage is to the self-interest of employers because it is the necessary means of gaining and keeping the labor

they want to employ. In overbidding the competition of other potential employers for labor, it attracts workers to come to work for them and it removes any incentive for their present workers to leave their employ. This is because it eliminates the artificial demand for labor by the employers who depend on a below-market wage in order to be able to afford labor. It is, as I say, identically the same in principle as the bidder who wants the painting at an auction raising his bid to prevent the loss of the painting to another bidder not able or willing to pay as much. The higher bid is to his self-interest because it knocks out the competition. In the conditions of a labor shortage, which necessarily materializes if wage rates go below the point corresponding to full employment, the payment of higher wages provides exactly the same benefit to employers.

On the basis of the preceding discussion, and also discussion in Parts B and C of Chapter 13, it should be clear that average money wage rates are determined neither by worker need nor by employer greed, but, basically, by the quantity of money in the economic system and thus the aggregate monetary demand for labor, on the one side, and by the number of workers willing and able to work, on the other—that is, by the ratio of the demand for labor to the supply of labor. It should also be clear that in a free labor market, money wage rates can fall no lower than corresponds to the point of full employment.

Two points should be realized in connection with the principle that it is against the self-interest of employers to allow wage rates to fall below the point that corresponds to full employment. First, the operation of the principle does not require that full employment be established throughout the economic system before wage rates cease to fall. On the contrary, the principle applies to each occupation and, still more narrowly, to each occupation within each geographical area. For example, the wage rates of carpenters in Des Moines can fall no further than corresponds to the point of full employment of carpenters in Des Moines. Any further fall would create a shortage of such carpenters and thus would be prevented or quickly reversed, even though there might still be major unemployment in other occupations or in other geographical areas.

Second, the operation of the principle need not be feared as possibly serving to bring about the establishment of subsistence wages through the back door, so to speak. By this, I mean that so long as unemployment exists, there is room for wage rates to fall without the creation of a labor shortage. And in a free market, wage rates would in fact fall in such circumstances. This is because in such circumstances, the self-interest of the

employers, and also of the unemployed, would operate to drive them down. It should not be thought, however, that the fall in wage rates in these circumstances meant that the conditions of supply and demand were capable of accomplishing the human misery that Marxism attributes to the alleged arbitrary power of businessmen and capitalists.

It should be recalled that we saw in Chapter 13 that a drop in wage rates to the full employment point does not imply any drop in the average worker's standard of living. That is, it does not imply any reduction in the goods and services he can actually buy—any reduction in his so called real wages—because the elimination of unemployment that the fall in wage rates brings about means more production and a fall in costs of production, both of which mean lower prices. Indeed, we saw that it is likely that real wages actually rise with the elimination of unemployment, even in the short run, because not only do prices fall as much as, or even more than, wages, but also the burden of supporting the unemployed is eliminated, with the result that disposable, take-home pay drops less than gross wages and less than prices.⁵³ When these facts are kept in mind, it is clear that insofar as market conditions require a fall in wage rates, they are, if anything, at the same time operating to raise the average worker's standard of living further above subsistence, not drive it down toward subsistence.⁵⁴

2. Determination of Real Wages by the Productivity of Labor

With the Marxian version of the iron law of wages now out of the way, it is possible to turn to the exposition of the productivity theory of wages proper. Chapter 13's analysis of what happens to real wages when money wages fall in the course of eliminating unemployment provides a good beginning, because it points the way to an understanding of the role of the productivity of labor in determining real wages. In Chapter 13, we saw that despite the fall in money wage rates, real wage rates—on a gross basis—stayed the same. (On a net basis, of course, they increased, because of the elimination of the burden of supporting the unemployed.)⁵⁵

Real wages stayed the same in the analysis of Chapter 13 because the productivity of labor remained the same. This was responsible for the fact that the employment of additional workers resulted in an equal proportional increase in the production and supply of consumers' goods and thus, in the face of constant demands for consumers' goods and labor, in a fall in the prices of consumers' goods in the same proportion as the fall in wage rates. This left the purchasing power of wages—real wages—unchanged. In other words, with a constant productivity

of labor, increases in the supply of labor and consumers' goods take place in the same proportion and cause equal reductions in wage rates and prices in the face of constant demands for labor and consumers' goods, leaving real wages the same.

We shall now see that not only in the case of the elimination of unemployment through a fall in wages and prices, but in all cases, *real wages are determined primarily by the productivity of labor*—i.e., by the output of goods and services per unit of labor. This conclusion follows from the very nature of real wages.

Real wages—the goods and services the worker can buy with his money wages—are, in the first instance, determined by the relationship between wages and prices. They can be expressed as the ratio of wages to prices. The higher are wages relative to prices, or equivalently, the lower are prices relative to wages, the more can the worker's money wages buy. All this is expressed in the formula

$$\text{Average Real Wage Rate} = \frac{W}{P}$$

where W is the average money wage rate, and P is the general consumer price level.

We can understand how the productivity of labor operates to determine real wages if we once again employ the formulas for money wages and the price level, namely:

$$W = \frac{D_L}{S_L}$$

and

$$P = \frac{D_C}{S_C}.$$

In these equations, of course, D_L is the aggregate demand for labor, as manifested in a definite total expenditure of money to employ labor in the economic system, that is, in total payrolls of a given size; S_L is the aggregate supply of labor, as manifested in a definite total quantity of labor employed; D_C is the aggregate demand for consumers' goods, as manifested in a definite total expenditure of money to buy consumers' goods; and S_C is the aggregate supply of consumers' goods, as manifested in a definite total quantity of consumers' goods produced and sold.

We can begin by holding everything constant but the productivity of labor, which, for the sake of simplicity, we can assume doubles over the course of some period of time. Thus, we assume that the money supply is the same and therefore that the aggregate monetary demands for labor and consumers' goods are the same. We also assume that the size of the population and the number of workers employed are the same. As I say, everything is

assumed to be the same except the productivity of labor, which is assumed to double. This is *Case 1*.

Using asterisks to denote fixity or lack of change, we see the results of *Case 1* in the following equations:

$$\frac{DL^*}{S_L^*} = W^*$$

$$\frac{DC^*}{2SC} = \frac{P}{2}$$

The result of prices halving while money wages remain the same is a doubling of average real wages. For inasmuch as

$$\frac{W}{P} = \text{Average Real Wage Rate},$$

it follows that

$$\frac{W^*}{\frac{1}{2} \times P} = 2 \times \text{Average Real Wage Rate}.$$

Case 1 shows that with the demand for and supply of labor the same, average money wage rates remain the same. It also shows, and this is critical, that the effect of a doubling of the productivity of labor, given the employment of the same number of workers, is a doubling of the supply of consumers' goods produced and sold. Indeed, since the productivity of labor is the output per unit of labor, it can be expressed by the following equation:

$$\text{Productivity of Labor} = \frac{SC}{S_L}.$$

The meaning of this equation is that the productivity of labor is reflected in the ratio of the supply of consumers' goods produced and sold to the supply of labor employed. The higher is the productivity of labor, the greater is the supply of consumers' goods produced and sold relative to the supply of labor employed. With S_L fixed, a doubling of the productivity of labor means a doubling of SC . That is, if the supply of labor employed is the same and the productivity of labor doubles, the supply of consumers' goods produced and sold doubles. In equation form,

$$2 \times \text{Productivity of Labor} = \frac{2SC}{S_L^*}.$$

Now, in the face of an unchanged demand for consumers' goods, the doubling of the supply of consumers' goods has the effect of halving the prices of consumers' goods and thus of doubling the buying power of the unchanged average money wage rates—that is, of doubling average real wage rates. Stating matters somewhat more broadly, the doubled productivity of labor doubles

real wages by virtue of doubling the supply of consumers' goods relative to the supply of labor and thereby halving the prices of consumers' goods relative to wage rates.

We see much more in *Case 1* than the fact that when the productivity of labor doubles, real wages double. Obviously, the general principle that is present in *Case 1* is that *real wages vary directly with the productivity of labor*, whatever it may be. This is because if the productivity of labor had increased by a factor of five or ten, rather than by a factor of two, and that had been the only change, then prices would have fallen to a fifth or a tenth, instead of to half, while money wage rates stayed the same. And thus real wage rates would have increased by a factor of five or ten, instead of two, precisely in accordance with the increase in the productivity of labor. This is because at a fifth or tenth of the initial price level, the same money wages would buy five or ten times more, respectively. (By the same token, to take an example of a fall in the productivity of labor, if the productivity of labor had halved, and that had been the only change, then the supply of consumers' goods would also have halved, and prices would have doubled while money wage rates remained the same. In this case, real wages would have halved, in accordance with the halving of the productivity of labor.)

Now that we have seen the effect of a rise in the productivity of labor in the context of a constant quantity of money and thus constant monetary demands for labor and consumers' goods, it is important to consider the effect of an increase in the quantity of money and the monetary demands for labor and consumers' goods. Once again, for the sake of simplicity, we assume that the magnitudes which increase neatly double. To isolate the effect of their increase we now assume that both the productivity of labor and the number of workers employed remain the same. This is *Case 2*, whose implications are shown in the following equations:

$$\frac{2DL}{S_L^*} = 2W$$

$$\frac{2DC}{S_C^*} = 2P.$$

In this case, where the supply of labor employed is unchanged and there is no increase in the productivity of labor, there is also no increase in the supply of consumers' goods. Hence, where the supply of consumers' goods is shown, it is accompanied by an asterisk. All that occurs in this case is that, in the face of unchanged supplies of labor and consumers' goods, the doubling of the quantity of money, and the consequent doubling of the aggregate demands for labor and consumers' goods, succeeds in

doubling both wage rates and prices, with the result that average real wages remain absolutely unchanged, for

$$\frac{2W}{2P} = \text{Average Real Wage Rate}^*.$$

What is important about *Case 2* is that it shows that, in sharpest contrast to an increase in the productivity of labor, a rise in money wages by itself does *not* represent any rise in real wages. The rise in money wages here is the result of an increase in the quantity of money, which operates to raise prices fully as much as wages, thus leaving real wages unchanged. In *Case 2*, the doubling of the quantity of money and the aggregate demands for labor and consumers' goods serves to double prices along with wages, leaving the real wages of the average worker absolutely unchanged. Obviously, the result of unchanged real wages would apply to *any* increase in the quantity of money and the aggregate demands for labor and consumers' goods. So long as wages and prices both increase in the same proportion, whether by two or by two hundred, or by any other number, the higher wages buy no more than did the lower wages of the past.

Now that we have considered the effects of an increase in the productivity of labor and in the quantity of money separately, in *Cases 1* and *2*, it is time to consider a case in which both factors operate side by side. This we do in *Case 3*. In this case, we assume that over a period of years *both the productivity of labor and the quantity of money double*, and that these changes once again respectively result in a doubling of the supply of consumers' goods produced and sold and in a doubling of the monetary demands for labor and consumers' goods. The substance of this case appears in these two equations:

$$\frac{2D_L}{S_L^*} = 2W$$

$$\frac{2D_C}{2S_C} = P^*.$$

When the results of these two equations are combined, the effect on average real wages is shown to be

$$\frac{2W}{P^*} = 2 \times \text{Average Real Wage Rate}.$$

Thus, in *Case 3*, we find that once again average real wages double. They double because in contrast to *Case 2*, the doubling of money wages is accompanied by a general consumer price level that is unchanged. What makes it possible for the general consumer price level to remain unchanged, in the face of a doubled quantity of money and a doubled aggregate demand for consumers' goods, is *the doubling of the productivity of labor*. This causes the supply of consumers' goods to double as the demand

for them doubles, and so leaves their price level unchanged. In effect, the doubled quantity of money and the doubled aggregate monetary demand for labor that it causes come up against an unchanged supply of labor and thus double average money wage rates, but thanks to the doubled productivity of labor, the doubled quantity of money and the doubled monetary demand for consumers' goods that it causes come up against a doubled supply of consumers' goods and thus leave the average of consumers' goods prices unchanged. (It should be realized that the doubling of the productivity of labor also leaves average unit costs unchanged despite the doubling of wage rates, for the doubled wage per worker is spread over double the number of units produced per worker.)

The essential point to realize is that *the source of the rise in real wages is always the rise in the productivity of labor*, not the increase in the quantity of money and the consequent increase in money wage rates. What is also very important to realize is that *the way the rise in the productivity of labor raises real wages is not by raising money wages, but by reducing prices!*

It is the increase in the quantity of money that increases money wages, not the increase in the productivity of labor. The increase in the productivity of labor increases money wages only insofar as it serves to increase the production of the monetary commodity under a system of commodity money, that is, only indirectly, insofar as it is the cause of an increase in the quantity of gold or silver money. Apart from this, the rise in the productivity of labor operates to reduce prices even in conditions such as those of *Case 3*, in which prices do not actually fall.

In such a case, it operates to reduce prices not in comparison with what they were, but in comparison with what *they otherwise would have been*. The fact that prices are unchanged in *Case 3*, even though the quantity of money and the demand for consumers' goods has doubled, thereby tending to make prices double, is the result only of the fact that the doubling of the productivity of labor simultaneously operates to cut prices in half. Prices are unchanged only as the result of being halved from the doubled level that the increase in the quantity of money and the monetary demand for consumers' goods would otherwise have made them reach.

The essential role of the productivity of labor in determining real wages is no less present if we further increase the complexity of our analysis to allow for changes in the supply of labor. If the productivity of labor remains constant, while the supply of labor employed increases, and, at the same time, the quantity of money and the aggregate monetary demands are constant, then money wages and prices both fall to the same extent, leaving average real wages unchanged. Indeed, we have already considered precisely this case in our discussion

of the elimination of unemployment.⁵⁶

If, when the supply of labor employed increases, the productivity of labor also increases, while the quantity of money and the aggregate monetary demands stay the same, then prices fall more than wages, for the supply of goods increases to a greater extent than the supply of labor. In this case, real wages rise once again, in accordance with the rise in the productivity of labor. For example, if both the supply of labor and the productivity of labor were to double, while the quantity of money and the respective aggregate monetary demands for labor and consumers' goods were to remain unchanged, then average money wage rates would fall to one-half of their initial height, reflecting the doubling of the supply of labor, while the general consumer price level fell to one-fourth of its initial height, reflecting the quadrupling of the supply of consumers' goods that ensues when twice the workers each on average produce double. Thus, once again, average real wages would double, in conformity with the doubling of the average productivity of labor.

The case which has actually occurred in the world in most periods since the end of the Dark Ages, and in a very pronounced way in the last two hundred years, is that the supply of labor, the productivity of labor, and the quantity of money and the respective aggregate monetary demands all increase at the same time. In this case, depending on the extent of the increase in the quantity of money and the aggregate monetary demands, money wage rates may still fall, while prices fall further; or money wage rates may remain constant, while prices alone fall; or money wage rates may increase, while prices fall, remain constant, or even rise—depending on how great is the increase in the quantity of money and the aggregate monetary demands for labor and consumers' goods. In all these possible cases, real wages will still be found to vary precisely with the variation in the productivity of labor, for it is the productivity of labor that determines the supply of consumers' goods relative to the supply of labor, and thus the prices of consumers' goods relative to wage rates.

The essential role of the productivity of labor in determining real wage rates can now be shown more abstractly, by means of the following simple algebraic derivation.

We already have established the following equations:

$$(1) \quad \text{Average Real Wage Rate} = \frac{W}{P},$$

$$(2) \quad W = \frac{DL}{SL},$$

and

$$(3) \quad P = \frac{DC}{SC}.$$

If we now substitute equations (2) and (3) into equation (1), we obtain

$$(4) \quad \text{Average Real Wage Rate} = \frac{DL}{SL} \div \frac{DC}{SC}.$$

Next, by the arithmetical rule of inverting and multiplying when dividing by a fractional expression, we obtain

$$(5) \quad \text{Average Real Wage Rate} = \frac{DL}{SL} \times \frac{SC}{DC}.$$

On the basis of the fact that quantities can be multiplied in any order, equation (5) is equivalent to

$$(6) \quad \text{Average Real Wage Rate} = \frac{SC}{SL} \times \frac{DL}{DC}.$$

The supply of consumers' goods relative to the supply of labor, is, of course, the expression of the productivity of labor. The demand for labor relative to the demand for consumers' goods can be called the "distribution factor," for want of a better description. It represents the extent to which wage payments are the source of consumption expenditure versus other sources of consumption expenditure, such as dividend and interest payments. Thus we have, finally,

$$(7) \quad \text{Average Real Wage Rate} = \text{The Productivity of Labor} \times \text{The Distribution Factor.}$$

which expresses the fact that real wages are the product of the productivity of labor times the "distribution factor."

A moment's reflection shows that the productivity of labor is by far the more important determinant of real wages, for it has no fixed limit. It can be increased to whatever extent the human mind is capable of improving the capital equipment by means of which labor produces. The distribution factor, on the other hand, has a maximum potential limit of less than one (inasmuch as there must be some consumption on the part of the owners and creditors of business firms or they would have no motive to conduct production), and has probably been fairly close to its limit in the United States and Great Britain since the middle of the eighteenth century.⁵⁷ As will be shown in subsequent discussion, the distribution factor is the more favorable to wage earners, the higher is the economic degree of capitalism, i.e., of saving and productive expenditure relative to sales revenues.⁵⁸

Thus, we have traced the influence of the productivity of labor on real wages first in isolation and then alongside the operation of changes in the quantity of money and the respective monetary demands for labor and consumers' goods, as well as changes in the supply of labor. Whatever the other factors present, the one that always explained the change in average real wages was the

productivity of labor. And now, finally, we have seen the decisive role of the productivity of labor set forth as an algebraically derived general principle.

3. The Foundations of the Productivity of Labor and Real Wages: Capital Accumulation and Its Causes

The productivity of labor is not the ultimate explanation of real wages; it itself has causes. In the first instance, of course, it depends on the quantity and quality of the equipment and materials with which the average worker works, i.e., on the supply of capital goods per worker. Without the appropriate capital goods, products either cannot be produced at all or can be produced only with the expenditure of far more labor per unit of product. For example, automobiles cannot be produced at all without a preexisting supply of various metals and tools for shaping metal. Without moving assembly lines and all manner of complex equipment, their production requires far more labor per unit of output than with such facilities.

The supply of capital goods, I will show, is the result of the joint operation of two further causes: (1) *the economic degree of capitalism*—in particular, the extent to which this results in the economic system concentrating on the production of capital goods relative to the production of consumers' goods; (2) *the efficiency of the economic system in using existing capital goods*. (This latter cause, as we shall see, subsumes technological progress.) I will also show that these two causes in turn depend, still more fundamentally, on respect for property rights and the consequent security of private property, and on the degree of rationality in a society—in short, on the values of freedom and reason.

Saving as a Source of Capital Accumulation

As I have indicated previously, in describing it as the ratio of Marx's M to his M' , the economic degree of capitalism refers to the proportion of sales revenues and incomes in the economic system that is *saved and productively expended*—that is, used in the purchase of capital goods and labor by business firms, as opposed to being expended for consumers' goods. It is the measure of the extent to which people act capitalistically, i.e., buy for the sake of subsequently selling (implicitly, of course, at a profit). In determining the proportions in which money is spent to buy capital goods relative to consumers' goods, saving and productive expenditure determine the proportions in which the economic system devotes its existing ability to produce to the production of capital goods relative to the production of consumers' goods.

As an illustration of this last point, the extent to which a firm with consumers' goods divisions and capital goods divisions divides its efforts between the two types of

products depends on the relative demands for these products. For example, General Motors will devote a larger proportion of the labor of its employees and of its existing capital goods to the production of capital goods, like diesel locomotives and trucks, and a smaller proportion to the production of consumers' goods, like passenger automobiles, if the demand for diesel locomotives and trucks rises relative to the demand for passenger automobiles.⁵⁹

The operation of this principle does not require that firms have both capital goods divisions and consumers' goods divisions. A rise in the demand for capital goods relative to the demand for consumers' goods will favor firms and industries that produce capital goods relative to firms and industries that produce consumers' goods. Through the operation of the uniformity-of-profit principle, this will bring about a shift of capital and labor from the production of consumers' goods to the production of capital goods. For example, to take the case of an industry in which some firms concentrate on the production of capital goods and others on the production of consumers' goods, a rise in the demand for factory and office buildings relative to the demand for residential housing will favor the branches of the construction industry that concentrate on factory and office buildings. As a result, a larger part of the construction industry will tend to devote itself to this type of construction. Similarly, a rise in the demand for the machinery and equipment used by business firms relative to the demand for home appliances will favor the producers of the former relative to the producers of the latter, and thus will have a similar effect on how existing means of production are employed. And, of course, the total capital invested in industries producing capital goods can be increased by the withdrawal of capital from other industries where it had been devoted to the production of consumers' goods.

Thus, in addition to firms with both consumers' goods and capital goods divisions being induced to concentrate more heavily on the production of capital goods, the operation of the uniformity-of-profit principle causes labor and capital to be withdrawn from firms and industries exclusively devoted to the production of consumers' goods and transferred to firms and industries exclusively devoted to the production of capital goods, if the demand for capital goods rises relative to the demand for consumers' goods.⁶⁰

As explained in Chapter 4, the proportion of its efforts that an economic system devotes to the production of capital goods is vital in determining whether or not it accumulates capital goods.⁶¹ Capital goods are constantly being consumed in production (and, indeed, by virtue of mere exposure to nature): materials and supplies are used up; machinery, factories, and buildings and

installations of all kinds wear out or run down. If these capital goods are to be replaced, they must be replaced out of production itself. Just as a farmer must replace the seed he consumes in the planting of his crop, out of the crop itself, so in a modern economic system, the steel mills and cement factories, the inventories of wheat and flour, and so on—all the factories, equipment, materials, and supplies—that are consumed in production must be replaced out of production. In other words, if the supply of capital goods is merely to be maintained intact—if the productive consumption of capital goods is to be offset—it is necessary to devote some definite, and more or less considerable, proportion of the existing means of production to the production of capital goods.

What this means, for example, is that some proportion of the output of steel mills and cement factories and so forth must be devoted to the production of steel mills and cement factories and so forth, in order to keep up the number and productive capacity of such plants. By the same token, some proportion of the economic system's production must take such forms as the production of steel sheet to replace the supply of steel sheet consumed in the production of automobiles, and of iron ore to replace the supply of iron ore consumed in the production of steel sheet.

The proportion of existing means of production that must be devoted to the production of capital goods in order to offset their productive consumption I call *the maintenance proportion*. If the proportion of existing means of production devoted to the production of capital goods equals the maintenance proportion, then the economic system produces as large a supply of capital goods as it consumes and thus succeeds in maintaining its supply of capital goods intact. If the proportion of existing means of production devoted to the production of capital goods exceeds the maintenance proportion, then the economic system produces more capital goods than it consumes and thus succeeds in increasing its supply of capital goods. If the proportion of existing means of production devoted to the production of capital goods falls short of the maintenance proportion, then the economic system produces a smaller supply of capital goods than it consumes and thus suffers a reduction in its accumulated stock of capital goods. Assuming a constant population and supply of labor, in the first case the economic system is *stationary*; in the second, it is *progressive*; in the third, it is *retrogressive*. In the first case, because the supply of capital goods remains the same, the productivity of labor and the general level of real wages remain the same. In the second case, because of capital accumulation, the productivity of labor and the general level of real wages increase. In the third case, because of capital decumulation, the productivity of

labor and the general level of real wages decrease.⁶²

Figure 14-4 illustrates the nature of a stationary economic system. In Figure 14-4, I assume that the existing supply of capital goods and labor—namely, IK of capital goods plus IL of labor—can be used to produce varying combinations of capital goods and consumers' goods ranging from $2K$ of capital goods and $0C$ of consumers' goods, at one extreme, to $0K$ of capital goods and $2C$ of consumers' goods, at the other extreme. These extremes are the values that would result if 100 percent of the existing supply of capital goods and labor were devoted to the production of capital goods, and 0 percent to the production of consumers' goods, and vice versa.

For the sake of simplicity, I assume that all the capital goods in existence at the beginning of a year are productively consumed in that year. Thus, by implication, I further assume (also for the sake of simplicity) that the maintenance proportion is one-half, for the replacement of IK of capital goods out of an output that is equivalent in size to $2K$ of capital goods is, of course, half of that output. Figure 14-4 represents a stationary economic system, because in each year the relative production of capital goods is one-half, precisely equal to the maintenance proportion, while the relative production of consumers' goods is, of course, also one-half. Thus, the supply of capital goods remains stationary.

Figure 14-4 illustrates the previous proposition that the relative production of capital goods and consumers' goods is in accordance with the relative demands for capital goods and consumers' goods. The downward sloping arrows in Figure 14-4 trace the transformation of existing capital goods and of labor into their products—namely, further capital goods, shown on the left, and consumers' goods, shown on the right. The proportions shown in Figure 14-4, of 50 percent and 50 percent in the relative production of capital goods and consumers' goods in each year, are in response to the fact that the demands for capital goods and consumers' goods in each year are 500 and 500 respectively. (These numbers can be thought of as abstract monetary units. As I stated in Chapter 13, each such unit could be taken as representing a billion dollars a few years back, and ten billion dollars today. It makes no difference which, just so long as the size is held fixed at some definite amount and is large enough so that the example can be understood as referring to the economic system as a whole.) It is in response to these demands of 500 and 500, which each represent one-half of an assumed total aggregate monetary demand of 1,000 each year for capital goods and consumers' goods taken together, that the utilization of existing capital goods and labor is 50 percent for the production of capital goods and 50 percent for the production of consumers' goods.

Figure 14-4
The Relative Production of Capital Goods in a Stationary Economy

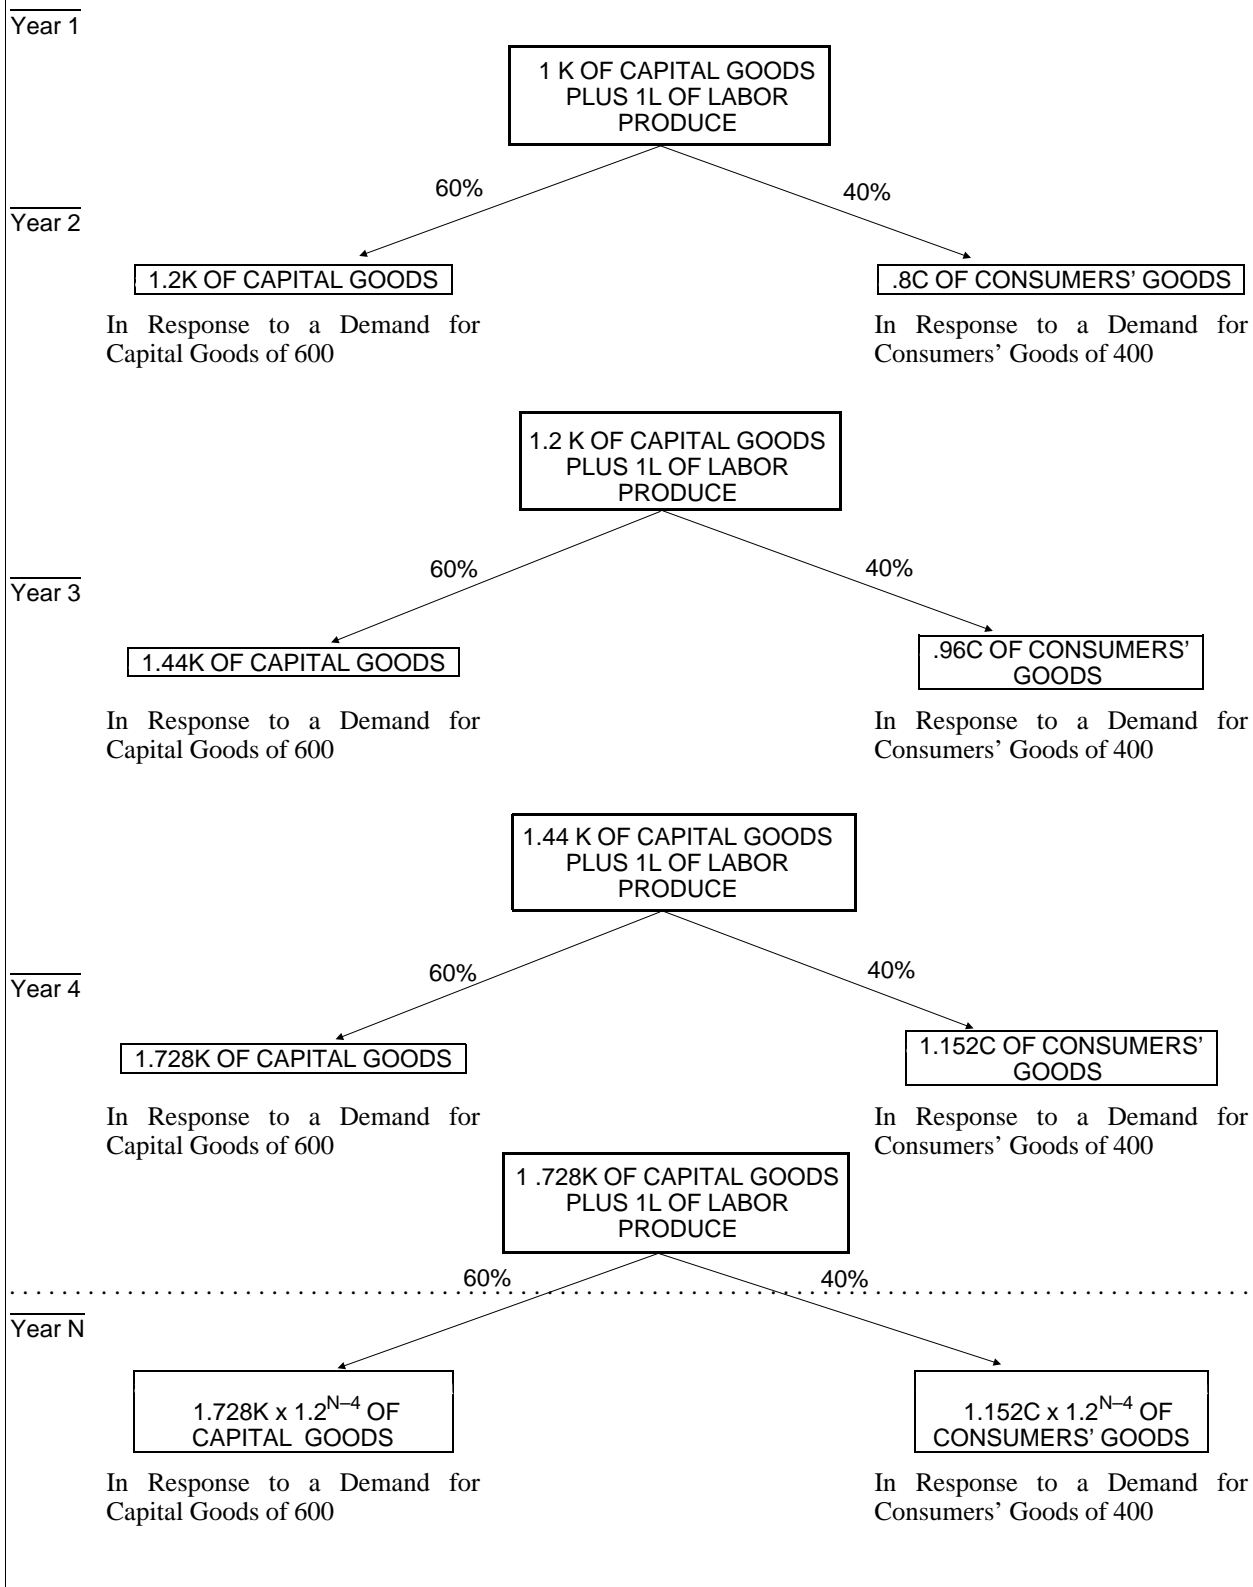

Figure 14-5
The Relative Production of Capital Goods in a Progressing Economy

In Figure 14–4, the capital goods and labor of each year are devoted to the production of capital goods and consumers' goods which become available for sale at the beginning of the following year. It is the relative demands for capital goods and consumers' goods in the following year, assumed to be correctly anticipated in the present year, that govern the relative disposition of capital goods and labor in the present year. Thus, the IK of capital goods plus IL of labor which exist in *Year 1*, produce IK of capital goods and IC of consumers' goods which become available for sale and are sold at the beginning of *Year 2*, each for 500. Thereupon, the producers in *Year 2* begin a new round of production, with the aid of the IK of capital goods that has been purchased for 500 and with the aid of a fresh IL of labor. In the course of production in *Year 2*, the fresh IK of capital goods is, of course, productively consumed in producing another fresh supply of IK of capital goods and IC of consumers' goods, which become available for sale and are sold at the beginning of *Year 3*—once again for 500 units of money each. The downward sloping arrows show a $50/50$ relative production of capital goods and consumers' goods in *Year 2*, this time in response to the $500/500$ relative demands for capital goods and consumers' goods that are made at the beginning of *Year 3*.

In *Year 3*, exactly the same story is repeated as takes place in *Year 2*, and will thereafter continue to be repeated indefinitely—down to *Year N*. Year in and year out, production begins with IK of capital goods and IL of labor; the capital goods are productively consumed in producing a fresh supply of IK of capital goods, along with a supply of IC of consumers' goods—in response to the relative demands for capital goods and consumers' goods of $500/500$.

Figure 14–5 depicts the conditions of a *progressing* economic system. As in Figure 14–4, the initial supply of capital goods, in *Year 1*, is assumed to be IK . But the labor and capital goods of *Year 1* are utilized very differently in Figure 14–5 than in Figure 14–4. In Figure 14–5, they are devoted 60 percent to the production of capital goods, instead of only 50 percent; and only 40 percent to the production of consumers' goods, instead of 50 percent. As a result, the supply of capital goods available to serve in production at the start of *Year 2* is $1.2K$ instead of only IK . By the same token, the supply of consumers' goods is $.8C$, instead of IC . The 20 percent larger supply of capital goods in *Year 2*, in comparison with the supply in existence at the start of *Year 1* in Figure 14–5, is the result of devoting 20 percent more resources to the production of capital goods than is necessary for the mere maintenance of their supply.

This change in the proportions in which capital goods and consumers' goods are produced is, of course, the

result of the change in the proportions in which they are demanded. In every year in Figure 14–5, the demand for capital goods and the demand for consumers' goods are 600 and 400 respectively, instead of 500 and 500 respectively, as was the case in Figure 14–4. The $60/40$ relative demand for capital goods and consumers' goods underlies their production in the $60/40$ ratio.

Now, as I have indicated, this change in the relative demands for capital goods and consumers' goods has its foundation in greater *saving*. For the source of the demand for capital goods, indeed, for all of productive expenditure, including the demand for labor, is saving. The demand for capital goods depends on the funds expended to buy capital goods not being expended to buy consumers' goods instead. That is, people who possess the necessary funds must abstain from consuming them—they must *save* them and employ them in productive expenditure for capital goods if the demand for capital goods is to be increased relative to the demand for consumers' goods. Precisely this represents the role of saving in capital accumulation. Namely, the degree of saving determines the relative demand for and production of capital goods.⁶³ I will have more to say about the role of saving, shortly, following the elaboration of the analysis depicted in Figure 14–5.

In Figure 14–5, I introduce the further assumption that the total productive ability of the economic system is *in proportion to the supply of capital goods*. Thus, when the supply of capital goods increases by 20 percent in *Year 2* in comparison with *Year 1*, the total ability of the economic system to produce also increases by 20 percent. As a result, the limiting combinations within which capital goods and consumers' goods can be produced are increased from $2K$ of capital goods, $0C$ of consumers' goods at one extreme, and $0K$ of capital goods, $2C$ of consumers' goods at the other extreme, to $2.4K$ of capital goods, $0C$ of consumers' goods at the one extreme and $0K$ of capital goods, $2.4C$ of consumers' goods at the other extreme. (The extremes, of course, are the products that would result from the use of the existing $1.2K$ of capital goods and IL of labor in proportions of 100 percent and 0 percent in the respective production of capital goods and consumers' goods or, alternatively, consumers' goods and capital goods.) Because the $60/40$ relative production of capital goods and consumers' goods is maintained, the actual total product of *Year 2* is $1.44K$ of capital goods and $.96C$ of consumers' goods, which are the supply of goods available at the start of *Year 3*. (These are the results found by respectively multiplying .6 and .4 times the alternative limiting production extremes of $2.4K$ and $2.4C$.)

Thus, $1.44K$ of capital goods is the supply of capital goods available with which to carry on production in

Year 3. And because production in *Year 3* is thereby carried on with a 20 percent larger supply of capital goods than was production in *Year 2*, the total productive ability of the economic system in *Year 3* increases by 20 percent *once again*, with the result that, under the prevailing $\frac{60}{40}$ relative production of capital goods and consumers' goods, the supply of capital goods and consumers' goods available for sale at the beginning of *Year 4* is $1.728K$ of capital goods and $1.152C$ of consumers' goods—a 20 percent increase over the respective supplies at the start of *Year 3*. (These are the results found by respectively multiplying .6 and .4 times the new limiting production extremes of $2.88K$ and $2.88C$, which are the products of $1.44K$ of capital goods and $1L$ of labor devoted 100 percent to the production of capital goods or, alternatively, 100 percent to the production of consumers' goods.)

Indeed, in the conditions depicted in Figure 14–5, production and the supply of capital goods will go on increasing by 20 percent *in every year*, with the 20 percent larger supply of capital goods in each year increasing the ability to produce in comparison with the preceding year by a further 20 percent, including the ability to produce capital goods. Thus, in Figure 14–5, in *Year N*, the supplies of capital goods and consumers' goods are shown as their respective amounts in *Year 4* times 1.2 compounded for the number of years elapsing between *Year 4* and *Year N*, namely, $N-4$, which is the exponent used in the compounding.

The *dynamic* effects of changes in the relative demand for and production of capital goods cannot be over-emphasized. Obviously, what is essential for capital accumulation to take place is that the supply of capital goods produced exceed the supply of capital goods productively consumed, and that for this to happen, the proportion of its efforts which an economic system devotes to the production of capital goods must exceed the maintenance proportion. This, of course, will occur only if the demand for capital goods relative to the demand for consumers' goods is sufficiently great, which in turn requires that the degree of saving be sufficiently high.

But increases in the supply of capital goods do *not* depend on *continuous increases in the relative demand for and relative production of capital goods*. Once the relative demand for capital goods rises to the point that their relative production exceeds the maintenance proportion, so that capital accumulation takes place, the productive ability of the economic system is increased, *including its ability to produce capital goods*. This greater ability to produce capital goods then results in *a further accumulation of capital goods*—provided only that the higher relative demand for and corresponding relative production of capital goods is maintained and

that the maintenance proportion does not rise.

In other words, once an economic system devotes a sufficiently large proportion of its efforts to the production of capital goods, it can go on accumulating capital goods on the strength of the larger supply of capital goods produced in the year before. For example, once the first railroads and steel mills were brought into existence on the basis of saving and a greater relative production of capital goods, the very existence of these additional capital goods made possible a further increase in the supply of capital goods. For once in the possession of these capital goods, the total ability of the economic system to produce was increased, and this included its ability to produce *further capital goods* no less than consumers' goods. Given the possession of the first railroads and steel mills, it became easier to produce railroads and steel mills, and virtually all other capital goods, than it was before, without them. On the basis of the greater productive ability made possible by their existence, the continuation of the *same*, higher relative production of capital goods had to result in a further increase in the supply of capital goods. Thus, once in possession of the first railroads and steel mills, it became possible to produce more, bigger, and better railroads and steel mills, and then, with the aid of these, to produce still more, still bigger, and still better railroads and steel mills, and so on and on, decade by decade—and, of course, to produce more capital goods of all kinds, for the principle applies throughout the economic system, to the ability to produce in general. Thus, to have continuous capital accumulation and economic progress, it is not necessary to go on raising the relative demand for capital goods and the relative production of capital goods, but only to maintain *a sufficiently high* relative demand and relative production.

This fact has major implications for the role of saving in capital accumulation. It implies that in an economic system with a given quantity of money and thus a given overall volume of spending for capital goods and consumers' goods combined, continuous increases in saving and decreases in consumption expenditure would not be necessary for the existence of capital accumulation, provided that the existing degree of saving, and thus the existing demand for capital goods relative to consumers' goods, were sufficiently high.

Given a relative demand for and production of capital goods that already exceeds the maintenance proportion, and total output that increases in proportion to the increase in the supply of capital goods, the effect of further increases in saving and the relative demand for and production of capital goods would be as *force to acceleration* is in the world of physical phenomena: that is, they would achieve *a more rapid rate* of capital accumulation and economic progress. For example, demand for

and production of capital goods in a $70/30$ ratio to consumers' goods, rather than the $60/40$ ratio assumed in Figure 14–5, would result in $1.4K$ of capital goods and $.6C$ of consumers' goods in *Year 2*, $1.96K$ of capital goods and $.84C$ of consumers' goods in *Year 3*, and $2.744K$ of capital goods and $1.176C$ of consumers' goods in *Year 4*—that is, an annual increase in production, and thus in the supply of capital goods and the ability further to increase production and the supply of capital goods, of 40 percent instead of 20 percent. (The figures of $1.4K$ of capital goods and $.6C$ of consumers' goods for *Year 2* result from the multiplication of the respective limiting extremes of $2K$ and $2C$ by $.7$ and $.3$ respectively. Similarly, the $1.96K$ of capital goods and $.84C$ of consumers' goods that would be available at the start of *Year 3* are respectively 70 percent and 30 percent of the increased limiting extremes of $2.8K$ of capital goods or $2.8C$ of consumers' goods that could alternatively be produced with the aid of an existing $1.4K$ of capital goods and $1L$ of labor, devoted 100 percent to the respective production of capital goods or, alternatively, consumers' goods. Likewise, the figures of $2.744K$ of capital goods and $1.176C$ of consumers' goods for *Year 4* are the result of multiplying $.7$ and $.3$ times the further increased respective limiting extremes of $3.92K$ or $3.92C$ that could be produced with the aid of an existing $1.96K$ of capital goods and $1L$ of labor, devoted 100 percent to the respective production of capital goods or, alternatively, consumers' goods.)

The rates of increase in production and in capital supply that I am assuming are, of course, unrealistically high, and substantially exceed even the record rates established by Japan and other East Asian countries in the last generation. This is the result of the simplifying assumptions I use.⁶⁴ Nevertheless, the essential point remains true that the greater the degree to which the relative demand for and production of capital goods surpasses the proportion required for the mere maintenance of the supply of capital goods, the more rapidly does the economic system tend to progress. For then, each year the production of capital goods exceeds the supply of capital goods consumed in production by a correspondingly wider margin. The production of each succeeding year then takes place with the aid of that much more of a larger supply of capital goods than did the production of the year before. And each year, by virtue of raising the productivity of labor that much more, the more enlarged supply of capital goods makes possible the production of a correspondingly still more enlarged supply of capital goods, as well as consumers' goods, in the following year.

In making the claim that production can increase in

proportion to the supply of capital goods, I may appear to be in contradiction of the law of diminishing returns. Actually, I am not. It is true that there can be diminishing returns to capital goods. However, this is not a necessary fact. Diminishing returns to capital goods are implied as a necessary fact only in the context of the employment of increasing quantities of capital goods of a *definite physical type* relative to labor. An increase in the supply of capital goods as such, however, does not mean an increase in the supply of some one, homogeneous factor of production employed. On the contrary, it can encompass the most radical changes in the technological methods of production. It can mean the substitution of steel for iron, titanium for steel, petroleum for coal, atomic power for petroleum, and so on. An increase in the supply of capital goods as a *genus* stands outside the context assumed by the law of diminishing returns insofar as its employment is accompanied by changes in the technological methods of production that are implemented. It is no more possible to speak of a necessary diminution of returns to capital goods as a *genus* than it is possible to speak of a necessary diminution of returns to human intelligence.

Indeed, even if one considers the case of a homogeneous capital good, such as iron ore of a given quality that has been mined, the law of diminishing returns can have no application insofar as the products made possible by a larger supply of iron ore may be steam engines instead of windmills, and then diesel engines and electric motors instead of steam engines, and so on, in one line of production after another. There can be diminishing returns to capital goods, but there need not be; in fact, there can even be increasing returns to capital goods as the result of advances in technology.

Only in the sustained absence of further technological progress must an additional supply of capital goods afford a less than proportionate increase in total productive power. Only in such circumstances does the additional supply of capital goods mean at some point increasing the supply of capital goods of the same types relative to labor. And this, as we shall see, results first in a slowing up and then in a complete cessation of the accumulation of additional capital goods, unless the proportion of the existing supply of factors of production devoted to their production should increase.

In connection with the above, it should be realized that even increases in the supply of capital goods of the same types relative to labor do not result in diminishing returns insofar as it is a question of extending the application of improved methods of production to a larger proportion of the labor force. For example, if initially 5 percent of

automobile factories are operating with the aid of moving assembly lines, the extension of the use of moving assembly lines to 10 percent, 20 percent, and ultimately, 100 percent, of the automobile factories will not result in diminishing returns. Diminishing returns set in only with the employment of more capital goods (of a given type) in conjunction with a given worker or group of workers, such as a given assembly-line team. Then, sooner or later, the result must be a less-than-proportionate increase in output.

As this fact indicates, it is consistent with this discussion that increases in the relative demand for and production of capital goods could be accompanied by an acceleration in the rate of capital accumulation and economic progress that itself took place at a decelerating rate. This would be the case insofar as the lapse of time was required to produce capital goods of different, technologically more advanced types than those presently in existence. Thus, for example, when the relative demand for and production of capital goods rose from a $60/40$ ratio to consumers' goods, to a $70/30$ ratio, the increase in productive ability could be in a lesser proportion than 1.4 to 1.2 insofar as the resulting 1.4K of capital goods were of the same kind as the 1.2K of capital goods that would otherwise have been produced and, in addition, had to be employed more heavily with the same, limited units of labor.

Technological Progress as a Source of Capital Accumulation

This brings me to the role of technological progress in capital accumulation. In order for the supply of capital goods to go on increasing on the basis of previous growth in the supply of capital goods, it is necessary that at some point further technological progress take place. In the conditions described in Figure 14–5, further technological progress is what ultimately keeps up the process of capital accumulation after the achievement of the rise in the relative production of capital goods from 50 percent to 60 percent and its resulting initial increase in the supply of capital goods. Further technological progress is what is ultimately required to offset the operation of the law of diminishing returns and thus for the existence of constant returns to a growing supply of capital goods. It is what is necessary for the process of a 20 percent larger supply of capital goods resulting in a 20 percent greater ability to produce and thus in a further 20 percent increase in the supply of capital goods with a consequent still further 20 percent increase in the ability to produce, to go on indefinitely.

In the prolonged absence of technological progress, the larger supply of capital goods from one year to the next would sooner or later result in an increase in total productive ability in the economic system that was less

than in proportion to the increase in the supply of capital goods. For the law of diminishing returns would set in. For example, in the absence of further technological progress, the increase in the supply of capital goods, say, in *Year 8* in comparison with *Year 7*, could well be accompanied by a less than proportionate increase in the ability to produce in *Year 8* in comparison with *Year 7*. On the basis of a 20 percent increase in the supply of capital goods in *Year 8*, production might increase by only 15 percent, say. This would mean that the subsequent increase in the supply of capital goods available for *Year 9* would also be only 15 percent. This lesser increase in the supply of capital goods in *Year 9* could, in turn, well be accompanied by an increase in the overall ability to produce that was less than in proportion to it, say, only 10 percent. Thus, the growing supply of capital goods would encounter diminishing returns, and as a result, the supply of capital goods would eventually stop growing, because the additional production out of which further capital accumulation takes place would be steadily diminishing.

In the absence of technological progress, the point must *always* sooner or later be reached where additional supplies of capital goods would increase the ability to produce by diminishing amounts, with the result that capital accumulation would eventually peter out, no matter how great the relative production of capital goods. In effect, in the absence of technological progress, the diminishing additional output per unit of additional capital goods would imply a falling average productivity of capital goods—that is, a falling ratio of output to the supply of capital goods. Since the supply of capital goods would still have to be replaced out of production, the further implication would be a corresponding rise in the proportion of output required to replace the capital goods consumed in production—viz., in the maintenance proportion. The maintenance proportion would tend to rise all the way to the point of equalling the relative production of capital goods, however high the latter might be. At that point, both capital accumulation and the increase in production would cease.

Technological progress, however, offsets the operation of the law of diminishing returns and makes possible the existence of long-term constant returns to a growing supply of capital goods. Exactly as I showed in connection with the limitless potential of natural resources, the law of diminishing returns continues to apply in a given state of technology, but not under the conditions of an improving state of technology.⁶⁵ And thus, because of the offset it constitutes to the law of diminishing returns, technological progress provides a parallel in the world of economic phenomena to the absence of friction in the world of physical phenomena. By virtue of its ability to

achieve constant returns to a growing supply of capital goods, technological progress stands in the same relationship to the ability of a larger relative production of capital goods to bring about capital accumulation as the absence of friction does to the ability of force to achieve acceleration in the world of physical phenomena. By virtue of technological progress, a one-time increase in the relative production of capital goods is capable of achieving an indefinitely long series of subsequent increases in the supply of capital goods. In effect, technological progress makes it possible for an increase in the relative production of capital goods to launch economic progress along a kind of inertial path, as it were.

Now, seen in this light, technological progress stands revealed as a *fundamental source of capital accumulation*. Without it, capital accumulation either cannot continue at all or can do so only by virtue of continuous increases in the relative demand for and production of capital goods, and in no case can be very substantial. If, for example, there had been no technological progress over the last two centuries, there could have been virtually no capital accumulation over this period. However high the relative production of capital goods in an economy whose technology was characterized by sailing ships and horse-drawn wagons, it would still have been simply impossible to produce any significant part of the capital goods that can be produced today, from the standpoint both of quantity and quality.

This is why, in Chapter 13, I ridiculed the secular-stagnationist variant of consumptionism as I did. It is simply absurd to believe that saving—the determinant of the relative production of capital goods—could somehow by itself provide the means of building modern steel mills and a modern railroad network and that fortunately these capital-using technologies appeared on the scene to provide uses for all the capital allegedly being generated by the process of saving. The truth is, as previously stated, that it is technological progress which is indispensable to the very existence of virtually all of the growing supply of capital goods that becomes available to implement further technological progress. It was precisely earlier technological advances in steel making, railroad building, and so forth, that underlay the growing supply of capital goods required to make possible the implementation of more advanced technologies in steel making, railroad building, and so forth later on. In effect, the technological advances of each decade played a crucial role in providing the growing supply of capital goods required to implement the technological advances of the following decade. Over the course of a period such as a generation or more, it should be obvious that it is the process of technological progress itself that is indispensable to the provision of the capital goods required for the

implementation of technological progress.

Regrettably, while the role of technological progress as a major, indispensable source of capital accumulation should now be obvious, the prevailing view in contemporary economics is that saving alone is the source of capital accumulation and that the role of technological progress is to provide “outlets” for the expanding supply of capital goods allegedly generated all by saving, and thereby to keep up the rate of profit.⁶⁶ In other words, the prevailing view is that underlying the consumptionist doctrine of secular stagnation.⁶⁷

Even when technological progress appears to be recognized, more or less in passing, as being responsible for capital accumulation, its essential role in connection with capital accumulation is still seen as that of keeping up the rate of return in the face of capital accumulation allegedly caused by saving. For example, Samuelson and Nordhaus write: “As a result of technological progress, capital per worker, output per worker, and wages per worker grow over time, yet the real interest rate does not decline. If no invention had occurred, perhaps Marx would have been proven correct in his prophecy of the falling rate of profit. But invention increases the productivity of capital and repeals the law of the falling rate of profit. In the race between diminishing returns and advancing technology, technology has won by several lengths.”⁶⁸ Thus, even though the role of technological progress in capital accumulation appears to be acknowledged in the opening words of the quotation, the acknowledgment is of no substance, and matters stand just where they stood before, with the essential role of technological progress seen as that of keeping up the rate of profit in the face of capital accumulation caused by saving. Indeed, when Samuelson and Nordhaus say that “as a result of technological progress, capital per worker . . . grow[s] over time, yet the real interest rate does not decline,” they should almost certainly be understood as meaning *not* that technological progress causes the growth in capital per worker, but that it is responsible for the fact that the growth in capital per worker caused by saving can go on without the real rate of interest declining.

This interpretation is also consistent with the fact that they, along with most other contemporary economists, regard the contribution of technological progress to the increase in production as *separate from and independent of* any contribution to capital accumulation. They see technological progress as contributing only to the increased production of *consumers’* goods. Indeed, when the importance of technological progress to the increase in the production of consumers’ goods is recognized, it is taken as the basis for *minimizing* the importance ascribed to capital accumulation! For example, Samuelson

and Nordhaus declare: “Thus of the 2.1 percent-per-year increase in output per worker, about .25 percentage points is due to capital deepening, while an astounding 1.85 percent per year stems from T. C. [technological change].” Elsewhere in their book, Samuelson and Nordhaus make clear that by “capital deepening,” they mean capital accumulation. This is when they describe capital deepening as “a rise in the capital-labor ratio,” i.e., as an increase in the supply of capital goods per worker.⁶⁹

Thus, Samuelson and Nordhaus, along with most other contemporary economists, end up in a position in which they fail to see not only the role of technological progress as a source of capital accumulation, but also the greater part of the role of capital accumulation itself in raising the productivity of labor. They believe that technological progress raises the productivity of labor directly, without any need for a corresponding additional quantity of capital goods.⁷⁰ I will show the error of this last view in the very next section of this chapter.

The Reciprocal Relationship Between Capital Accumulation and Technological Progress

It is necessary to stress that the ability of the economic system to implement advances in technology depends on the supply of capital goods it already possesses, which crucially depends on the economic degree of capitalism and on the closely related concept of capital intensiveness. Capital intensiveness in the economic system can be conceived of in terms of the ratio of the total value of accumulated capital in the economic system to—alternatively—aggregate sales revenues, wage payments, or consumption expenditures.⁷¹ It is the greater, the higher are these ratios.

The economic degree of capitalism and the degree of capital intensiveness in the economic system operate, as it were, as a kind of long-range “radar net” for technological progress—with cumulative long-run consequences for capital accumulation and the ability to implement technological advances, in that they determine which kinds of technologies can be picked up and implemented at any given time.

The fact that the ability of an economic system to implement technological advances depends on its existing supply of capital goods can be illustrated by a close analogy from the conditions of our lives as consumers. Thus, for example, a Mercedes 450 SE represents a more advanced technology in automobiles than, say, a Chevy Nova. If we ask what it is that stops people from implementing this more advanced technology, the answer is obviously not that they lack the necessary technological knowledge of how to drive a Mercedes. They already know perfectly well how to drive one. What stops them from doing so, obviously, is the fact that they lack the

wealth—the means—to implement this more advanced technology. They simply cannot afford to buy the Mercedes.

In just the same way, there are more advanced technologies in business that businessmen already know how to employ or could easily learn to employ, but which they cannot afford to adopt, because they lack the capital. For example, as von Mises used to say in his seminar, every farmer in India who has seen American movies showing tractors and harvesters knows that he too could benefit from the use of such equipment. Again, what stops him is not that he doesn’t know how to operate such devices (he could easily learn), but that he lacks the capital to purchase them. And, of course, as Say’s Law shows, what makes him lack the purchasing power to buy the necessary capital goods is precisely the inability of the economic system physically to produce them or to produce them in sufficient quantity. The possession of capital—more fundamentally, the physical ability of the economic system to produce capital goods—is thus vital to the ability of the economic system to implement more advanced technologies.

An outstanding example of this fact in our own economy is that the implementation of the technology involved in the production of space rockets and communications satellites, and all that may subsequently depend on them, would not be possible if there did not already exist a highly developed electronics industry, chemical industry, computer industry, transportation system, metallurgical industry, and electrical industry, and all the other industries necessary to the existence of these industries. The mere technological knowledge alone would not be sufficient to make possible the actual production of space rockets and communications satellites.

The fact that as the result of a higher economic degree of capitalism an economic system possesses a higher relative production of capital goods and is more capital intensive means that it is able to implement technologies that it otherwise would not have been able to implement. Its greater relative production of capital goods and greater capital intensiveness provide it with the necessary capital. For example, in the nineteenth century, Great Britain was the world’s most capital-intensive economy. It possessed the capital necessary to implement such highly capital-intensive technologies as railroading, and even to provide other countries with the means of doing so. If the British economy had had no greater capital intensiveness than, say, the economy of Italy, it would have been impossible for Britain to undertake railroading. The only possible source of the necessary capital would have been stripping other industries of their vital capital, and thus to end up actually reducing production overall. But with a sufficient degree of capital intensiveness in the British

economic system, the capital necessary for the first railroads was available without disrupting production elsewhere. Thus, Britain could have railroads and even provide them to others.

Now once the first railroads were built, the effect, of course, was to increase the economic system's overall ability to produce—to produce not just consumers' goods but also further capital goods, including the means for more, bigger, and better railroads. As previously stated, once the first railroads, steel mills, and so forth came into existence, it became easier to build more and bigger and better railroads, steel mills, and so forth, because their production could be undertaken with the aid of the first railroads, steel mills, and so forth. In other words, the achievement of a higher degree of capital intensiveness, like the closely related achievement of a higher relative production of capital goods, made possible an increase in production which was itself the source of a second increase in the supply of capital goods. Thus, the effects of greater capital intensiveness were and are cumulative. In any given period of time, greater capital intensiveness permits the adoption of technologies that otherwise could not be adopted. And then, the increase in production that results from the adoption of those technologies provides still more capital goods in the future, so that still more advanced technologies can be adopted—without the necessity of further increases in the degree of capital intensiveness.

On this basis, it should be clear that the relationship between capital accumulation and the ability to implement more advanced technologies is *reciprocal*. Technological progress is both a vital, indispensable source of capital accumulation and, at the same time, the ability to implement advances in technology depends on the existing supply of capital goods and, more fundamentally, on the relative production of capital goods and degree of capital intensiveness in the economic system.⁷² Technological progress is not implemented in a vacuum. A country which already annually produces, say, one-half of a ton of steel per capita is able to implement more advanced technological processes of production both in steel making and probably in all other branches of production than one which only produces a quarter of a ton per capita, and that country is able to implement more advanced technological processes of production than a country which only produces one-eighth of a ton of steel per capita; and it is the same with respect to the ability to produce in innumerable other lines of production, from aluminum and its products to zirconium and its products.

To take one final example, imagine, as was quite possibly the case, that all the technological knowledge required for the construction of the steel mills and oil

refineries of the kind constructed in the 1960s existed in 1920. Nevertheless, it would not have been possible to construct such steel mills and oil refineries at that time, at least not economically, if for no other reason than that it would have made too great a demand on the then existing supply of steel and petroleum products. Because the supply of capital goods was increasing, it was, however, possible to construct more advanced facilities for steel making and petroleum refining in the decade of the 1920s than had been possible in the previous decade. With the aid of the larger production of capital goods made possible by these more advanced facilities, it was then possible in the decade of 1930s to construct still more advanced facilities for the production of steel and petroleum than had been possible in the 1920s; and with the aid of the then still larger supply of capital goods made possible by these still more advanced facilities, it became possible in the next decade to implement further improvements in the production of steel and oil until, two decades later, it became possible to construct steel-making and petroleum-refining facilities of the type built in the 1960s.

As the preceding words suggest, it is not necessary that further technological progress occur concurrently in order to maintain the returns to additional capital goods. Probably, even in the present-day United States, several years could go by without further technological progress taking place, and the returns to additional capital goods would remain undiminished. In the case of a backward country, such as India, most likely decades could go by, and the returns to a larger supply of capital goods would not diminish, even though no new technological knowledge came into existence. This is because the growing supply of capital goods would make possible the implementation of already known technologies which it had not been possible to implement before because of a lack of a sufficient supply of capital goods. However, sooner or later, further technological progress is always necessary to maintain the productivity of capital goods.

What it is crucial to recognize in connection with real wages, which is our central concern in this chapter, is that capital accumulation and a rising productivity of labor depend on *a combination of technological progress and a sufficiently high economic degree of capitalism*, which latter is responsible both for a sufficiently high relative demand for and production of capital goods and for a sufficiently high degree of capital intensiveness.⁷³

The Economic Degree of Capitalism, the Wage “Share,” and Real Wages

It is important to realize in addition that the economic degree of capitalism determines real wages not only by virtue of its connection with capital accumulation and the

productivity of labor, but also by virtue of its connection with the so-called distribution factor—i.e., the relationship between the demand for labor and the demand for consumers' goods, and thus the proportion of consumer spending originating in wage payments.

The wages paid by business firms are paid by the business firms, not by the consumers, who buy the ultimate product of business firms. The wages are a part of *productive expenditure, not consumption expenditure*.⁷⁴ The higher the economic degree of capitalism—i.e., the larger the proportion of sales revenues and incomes saved and productively expended—the higher is not only the demand for capital goods relative to the demand for consumers' goods, but also the higher is the demand for labor relative to the demand for consumers' goods. For example, if the owners of a given firm, with sales revenues, let us say, of \$1 billion, pay themselves an annual dividend of \$50 million instead of \$100 million, and thus save and productively expend \$950 million instead of only \$900 million, their firm's demand for labor, as well as for capital goods, is bound to be larger. And it will be all the more enlarged relative to their own consumption expenditure, which is fully halved in this case. It should be obvious that to the extent that such behavior prevails in the economic system as a whole, the same conclusions apply. Thus, a rise in the economic degree of capitalism acts in a double way to raise real wages. It raises the wage share of consumption along with raising the productivity of labor. Both members of the equation determining real wages are increased.

The full contribution of the economic degree of capitalism to real wages can be described in terms of a simple equation that represents all of the essential elements of aggregate monetary demand. Thus,

$$\frac{M}{M'} = \frac{D_L + D_K}{D_C + D_K}.$$

The only new item in the equation is D_K , which is the aggregate demand for capital goods, D_L being the by-now-familiar aggregate demand for labor, and D_C the by-now-equally-familiar aggregate demand for consumers' goods. M and M' , of course, respectively represent the aggregate productive expenditures made by business and the aggregate sales revenues of business. The equation expresses the fact that these are the respective sums of D_L plus D_K and D_C plus D_K .

The twofold positive effect of a rise in the economic degree of capitalism on real wages can be illustrated in terms of this equation. Thus let us begin with an economic degree of capitalism of .8, reflecting an aggregate demand for capital goods of 500, an aggregate demand for labor of 300, and an aggregate demand for consum-

ers' goods of 500. The figure of .8 for the economic degree of capitalism equals the result of substituting the assumed numbers in the above equation. The assumed value of 500 for the demand for capital goods is, of course, substituted both in the numerator and in the denominator, inasmuch as the demand for capital goods is equally a part both of productive expenditure and of sales revenues. (For the most part, the numbers assumed merely repeat the numbers assumed in Figure 14-4. All that is added is the assumption that the aggregate demand for labor is 300—Figure 14-4 made no assumption about the demand for labor.) Thus, we have:

$$\frac{800M}{1,000M'} = \frac{300D_L + 500D_K}{500D_C + 500D_K}.$$

In these initial conditions, the 500 of demand for consumers' goods comes from the wage earners' consumption expenditure of their 300 of wages and the further consumption expenditure of 200 by businessmen and capitalists, out of such sources as dividend and interest payments.

Now let us observe the effect of a rise in the economic degree of capitalism to, say, .95. This comes about as the result of businessmen and capitalists becoming more future-oriented and thus reducing their consumption expenditures from 200 to 50, while correspondingly increasing their saving and productive expenditures from 800 to 950. We further assume that of the 150 of additional saving and productive expenditure, 100 is an additional demand for capital goods and 50 is an additional demand for labor, which the wage earners will add to their expenditure for consumers' goods. Thus, the aggregate demand for capital goods is now 600, just as in Figure 14-5, and the aggregate demand for consumers' goods is now 400, also just as in Figure 14-5. (The demand for consumers' goods falls only by 100, rather than by the 150 reduction in the consumption expenditure of businessmen and capitalists because part of the effect of the businessmen and capitalists consuming less is an increase of 50 in wages, which enables the wage earners to increase their consumption by that amount. Thus, total consumption is reduced only by 100, from 500 to 400. In the new circumstances the wage earners consume 350 and the businessmen and capitalists, 50.)

Inserting these numbers in the equation, we obtain

$$\frac{950M}{1,000M'} = \frac{350D_L + 600D_K}{400D_C + 600D_K}.$$

Here then, is a rise in the economic degree of capitalism and, as the direct result of it, a rise in the relative demand for and production of capital goods, which serves progressively to raise the productivity of labor and thus real wages, and, in addition, a rise in the so-called distri-

bution factor in favor of wage earners, from $\frac{300}{500}$ to $\frac{350}{400}$. Thus, as the economic degree of capitalism rises, we observe a twofold source of higher real wages, namely, the source of a rise both in the productivity of labor and in the “distribution factor.” Of course, the rise in the productivity of labor is potentially capable of continuing without fixed limit, thanks to the ability of capital accumulation to continue without fixed limit, on the strength of a rise in the relative demand for capital goods. In contrast the potential rise in the “distribution factor” is of a one-time, nonrepeatable nature and is extremely limited.

Other Factors, Above All Economic Freedom and Respect for Property Rights, as Sources of Capital Accumulation

In addition to the relative production of capital goods and technological progress as determinants of the supply of capital goods, and thus of the productivity of labor, there is, as mentioned, the general efficiency with which existing capital goods are employed—viz., *the productivity of existing capital goods*. By the productivity of capital goods, I mean, of course, the ratio of output to the supply of capital goods. Technological progress is obviously a major contributor to this factor and is subsumed under it. But it is not the only thing that contributes to it. In Chapter 4, I pointed out how the division of labor itself, in all the aspects in which it increases production in general, operates to increase the production and supply of capital goods.⁷⁵ Wider still, as Ricardo pointed out, increases in the supply of capital goods can be achieved by *anything* that operates to increase the overall ability to produce. In Ricardo’s words, “Capital is that part of the wealth of a country which is employed with a view to future production, and may be increased in the same manner as wealth.”⁷⁶

This means that capital accumulation can also result from such things as the adoption of free international trade, since free trade enables the same quantity of labor and capital goods to produce more, including more capital goods.⁷⁷ Indeed, it can result from the adoption of freedom of immigration. Freedom of immigration results directly in an increase in the total ability to produce—by virtue simply of adding to the supply of labor. In so doing, it adds to the ability to produce capital goods no less than to the ability to produce consumers’ goods. In a free, capitalist economy, it also ultimately results in a permanently higher productivity of capital goods and correspondingly lower maintenance proportion in the economic system, thanks to a larger absolute number of gifted people being available and motivated to pursue careers in science, invention, and business, and thereby to accelerate the rate of technological progress. In addition, it

makes it possible to carry the division of labor further throughout the economic system and thus to achieve the improvements in the production and supply of capital goods that result on this score as well.⁷⁸

As I indicated in Chapter 4, in the example of the isolated farmer who must use part of his crop as seed, the more efficient an economic system is in the utilization of its existing supply of capital goods—the higher the productivity of its existing capital goods—the greater is its ability to accumulate additional capital goods.⁷⁹ This is because a greater efficiency in the utilization of existing capital goods means that with any given supply of capital goods it can produce a larger total product, including a larger supply of capital goods for any given proportion of its productive efforts that it devotes to the production of capital goods. The effect of this, in turn, is that the proportion of its output which it needs to have in the form of capital goods in order to make possible the replacement of the capital goods consumed in production—its maintenance proportion—is correspondingly reduced. To whatever extent the economic system was already devoting to the production of capital goods a larger proportion of its efforts than was required for mere replacement, this reduction in the maintenance proportion further widens the margin by which it accumulates capital, and thus the rate at which it accumulates capital.

To illustrate this point, one need only imagine that in Figures 14–4 and 14–5, it became possible to produce with $1L$ of labor and each $1K$ of capital goods used in conjunction with $1L$ of labor not merely $2K$ of capital goods or, alternatively, $2C$ of consumers’ goods, but $3K$ of capital goods or $3C$ of consumers’ goods. Under these conditions, the maintenance proportion of the economic system would no longer be 50 percent, but only $33\frac{1}{3}$ percent. For a mere one-third of an output equivalent to $3K$ of capital goods would be sufficient to replace the $1K$ of capital goods productively consumed in producing that output. As a result, the economic system would become capable of accumulating capital even in the conditions of Figure 14–4—merely by continuing to devote half of its productive effort to the production of capital goods, for a 50 percent relative production of capital goods exceeds a maintenance proportion that has been reduced to $33\frac{1}{3}$ percent. In these circumstances, the supply of capital goods in *Year 2* of Figure 14–4 would be $1.5K$ instead of merely $1K$. In *Year 3*, continuing with a 50 percent relative production of capital goods and the same higher productivity of capital goods, the supply of capital goods would grow to $2.25K$, and so on. (The figure of $2.25K$ results from multiplying $.5$ by $4.5K$, which latter would be the output of $1.5K$ of capital goods and $1L$ of labor operating under the conditions of the higher productivity of capital goods and devoted 100

percent to the production of capital goods.) In Figure 14–5, of course, the effect of the improvement in efficiency and consequent reduction in the maintenance proportion to one-third would be a still more rapid rate of capital accumulation than had previously been possible with a 60/40 relative production of capital goods and consumers' goods, and one that would be correspondingly larger than the now enormously rapid rate achievable even with a 50 percent relative production of capital goods.

Nothing can be more vital than to realize that the fundamental source of capital accumulation is *economic freedom*—not only in connection with international trade and immigration, but across the board.

First, of course, it cannot be stressed too strongly that the demand for labor and capital goods, and, consequently, the wage share of consumption, the relative production of capital goods, and the closely related concept of the degree of capital intensiveness in the economic system, all depend on saving and provision for the future, as opposed to current consumption. Saving and provision for the future, in turn, depend on the freedom to enjoy one's property: they depend on respect for property rights and the consequent security of property. This is an indispensable basis of the motive to save and provide for the future.⁸⁰ If individuals could not count on benefitting from their saving and provision for the future, because the government or private bands could be expected to seize their wealth before they could enjoy it or its fruits, they would not save and provide for the future, or would do so to a far lesser extent. And to whatever extent they did continue to do so, they would do so in secret—in ways that could easily be concealed from the envious eyes of others, such as hoarding gems or precious metals, and thus in ways that would not provide material means for raising the productivity of labor.

However, as the preceding discussion of this section has shown, economic freedom and respect for property rights promote capital accumulation in ways beyond providing an environment in which people are motivated to save and invest, and thus to secure a sufficiently high relative production of capital goods and a sufficiently high degree of capital intensiveness. They do so no less *by virtue of increasing the output per unit of capital goods in the economic system and thus reducing the maintenance proportion* and allowing any greater actual relative production of capital goods to achieve capital accumulation.

Raising the productivity of capital goods is the result of economic freedom and respect for property rights not only in connection with international trade and immigration, which has already been shown, but also with respect

to other, wider phenomena. For example, the searching out and implementation of technological advances by businessmen comes under this heading. This is because such activity depends on the motive of profit and loss and on the freedom of competition, both of which, in turn, presuppose the existence of private ownership of the means of production.⁸¹

As we have seen, the incentive of profit and loss and the freedom of competition underlie all the benevolent effects of the operation of the uniformity-of-profit principle and, indeed, underlie and drive the entire price system.⁸² As we should now be able to understand, these benevolent effects of the uniformity-of-profit principle are dynamic. That is, they consist not only in raising the productivity of labor in the present, but also in permanently raising the productivity of existing capital goods and correspondingly reducing the maintenance proportion, and thereby powerfully contributing to capital accumulation and the continuing rise in the productivity of labor that comes from capital accumulation. Thus, the operation of the uniformity-of-profit principle is a leading source of capital accumulation. For so long as businessmen are inspired continually to introduce productive innovations of all kinds as the means of earning a premium rate of profit in the face of economic competition, the productivity of capital goods will be elevated and remain elevated.

The enormous contribution of the price system to capital accumulation becomes obvious when one recalls the destructive effects of socialism. We have seen that when private ownership of the means of production and the price system are destroyed by socialism, economic chaos results and thus the productivity of the existing supply of capital goods becomes so low and the maintenance proportion so high that capital accumulation becomes impossible, except at the price of mass murder, and even then only with the aid of an outside, capitalist world to provide vital supplies.⁸³

Furthermore, we have also seen, in contrast, that the more fully are property rights respected, the more powerfully do the incentives of profit and loss and the freedom of competition operate. This is because, to that extent, profits are not taxed away, nor are subsidies of any kind given by the government, and all industries are legally open to everyone. Thus, the incentive of profit and loss and the freedom of competition can operate with corresponding lack of diminution. Full respect for private property rights implies the maximum incentive to cut costs and increase output per unit of input, and thus to achieve the maximum possible efficiency in the use of existing capital goods.⁸⁴ (The freedom of profits from taxation, of course, also operates powerfully to increase the economic degree of capitalism and thus the relative

production of capital goods and degree of capital intensiveness in the economic system, because most of the profits left in the hands of business firms are plowed back into the purchase of capital goods and the payment of wages.)

Of course, even more fundamental than economic freedom as the foundation of capital accumulation is the degree to which a society values *human reason*. As I explained in Chapter 1, the prevalence of a substantial degree of rationality is required for the existence of economic freedom and respect for property rights. This is because it is the foundation of the view of man and the human individual as supremely valuable and as competent to run his own life, and thus as possessing individual rights which the government must respect. The degree of rationality also further underlies the willingness to save and provide for the future in that only the exercise of reason can make the future appear real in the present, which is necessary if people are to provide for it. Also it is the influence of reason and the acceptance of causality and human free will that makes it possible for people to come to regard themselves as self-responsible causal agents able to provide for the future and with an obligation to do so. And, of course, it is the acceptance of reason and causality that underlie all scientific and technological progress.⁸⁵

Thus, the ultimate foundations of a rising productivity of labor and rising real wage rates are *freedom and reason*.

It should be obvious that this discussion fully confirms the thesis previously advanced in the critique of the exploitation theory in Chapter 11, that the parties crucially responsible for the rise in real wages are *businessmen and capitalists*. It is they who are constantly on the lookout for more efficient methods of production and who provide the capital funds that ensure a sufficient relative production of capital goods and degree of capital intensiveness, and that constitute the demand for labor. As far as it relates to wage earners, the effect of their activities is entirely to raise real wages: it is to raise the demand for labor relative to the demand for consumers' goods and, far more importantly, continually to raise the productivity of labor through the accumulation of capital, the latter resulting from the combination of a greater relative production of capital goods and higher degree of capital intensiveness and the highest possible productivity of capital goods.

The present discussion has also fully confirmed the thesis of Chapter 9, that private ownership of the means of production and respect for property rights are to the self-interest of everyone, not just the owners of the means of production. In underlying the profit motive, competi-

tion, and saving and productive expenditure, and in making possible their fullest and most efficient functioning, private ownership of the means of production and respect for property rights make possible the rapid accumulation of capital and thus the continuous and rapid rise in the productivity of labor and real wage rates, and at the same time assure the highest possible share of consumption originating in wage payments.

Thus, what this discussion has confirmed is that private ownership of the means of production, respect for property rights, and economic freedom are in the interest of wage earners no less than businessmen and capitalists.

Unfortunately, it is one of the great ironies—and injustices—of history that while businessmen and capitalists and the institutions of capitalism have created the modern standard of living of the average wage earner, and are capable of raising it further without any fixed limit, the great majority of mankind has believed, largely under the influence of Marxism, that profits and interest are derived from the impoverishment of the wage earners, and that the institutions of capitalism represent legalized theft and plunder. The ultimate irony—and justice—of this state of affairs is that to the degree that these vicious and destructive beliefs are put into practice, those who hold them impoverish themselves. The greater their ignorance and envy, and the legalized looting and plunder that result, the more do they push themselves into poverty.

The Undermining of Capital Accumulation and Real Wages by Government Intervention

It is essential to realize the extent to which government intervention undermines capital accumulation, and with it the demand for labor and the productivity of labor, and thus real wages and the general standard of living.

The progressive personal income and inheritance taxes, and the corporate income and capital gains taxes, are paid mainly with funds that would otherwise have been saved and productively expended. Thus, their effect is to reduce the demand for capital goods and the demand for labor by business enterprises, and thus to reduce the economic degree of capitalism and the degree of capital intensiveness in the economic system. Consumption expenditure of the government and of those to whom it gives money replaces expenditure for capital goods and labor by business enterprises, and thus consumption expenditure of the employees of business enterprises. In accordance with this change in demand, the existing ability of the economic system to produce is diverted from the production of capital goods to the production of consumers' goods, and from the production of consumers' goods that the employees of business would have bought to the production of the consumers' goods that the government and its employees and dependents buy. Such taxes threaten

not only the economic system's ability to progress, but even its ability to produce sufficient capital goods to replace those that are used up in production—i.e., to remain stationary.

These taxes also greatly undermine the incentives to introduce improvements in efficiency in the economic system, as do government subsidies, antitrust laws, pro-union legislation, environmental legislation, and government regulation in general. In all these ways, government intervention operates to reduce output per unit of capital goods and thus to retard capital formation by this means too. The taxes reduce the rewards of economic success and thus discourage the efforts necessary to achieve it. At the same time, subsidies perpetuate inefficient methods of production by sustaining their practitioners. Thus, the taxes and the subsidies hold down the productivity of capital goods.

Furthermore, in depriving innovative small firms of the profits that would make possible their expansion, or more rapid expansion, most of these taxes also substantially reduce the force of competition in the economic system. They create a protective shelter around established firms that have already accumulated substantial capital and are now made more or less immune from the threat of new competition, since the potential competitors are prevented from accumulating capital, or from doing so as rapidly as they might have.⁸⁶ Essentially the same analysis applies to government regulation insofar as it is more difficult for small firms to comply with it, as when the regulations give an advantage to firms able to afford the employment of staffs of lawyers and accountants.

The antitrust laws stand in the way of business mergers that would achieve important economies and thereby render production more efficient. For example, the larger firm that results from a merger can often provide a sufficient volume of production to justify the purchase of machinery that the smaller firms which preceded it could not, or makes it possible to eliminate wasteful duplication in the use of existing equipment. In such ways, mergers make possible a more efficient use of capital. Preventing them prevents such more-efficient use of capital. In so doing, it retards capital formation.

Similarly, prounion legislation, in making it possible for the unions to prevent or delay the introduction of labor-saving machinery and more-efficient work practices, holds down the total output that otherwise could be produced in the economic system by the same quantity of labor working with the existing quantity of capital goods. In so doing, it holds down the size of the output that is available to meet whatever relative demand may exist for capital goods. So-called environmental legislation likewise provides numerous examples of reducing

output per unit of capital goods, such as depriving the capital and labor employed in the energy industry of its most productive uses by closing off vast territories to the very possibility of exploration and development, and imposing all manner of regulations on business in general that require the employment of additional capital and labor to accomplish a given result. All such regulations needlessly reduce output per unit both of labor and of existing capital goods, while correspondingly increasing costs per unit.⁸⁷ Indeed, in some cases business firms must invest once in order to produce their products, and the equivalent of a second time in order to be in compliance with the government regulations inspired by the pathological fears of the environmentalists.

Every government regulation, of whatever description, that needlessly raises costs, correspondingly reduces the output of the economic system and thus the efficiency with which existing capital goods are employed. This conclusion follows from the proposition established back in Chapter 6 that reductions in unit cost underlie increases in output in the economic system, by virtue of releasing labor and capital to produce more either of the good whose unit cost is reduced or of other goods.⁸⁸ The corollary of this proposition is that increases in unit cost operate to reduce output in the economic system. Both propositions also follow from the fact that with any given magnitude of aggregate productive expenditure, average unit cost in the economic system as a whole varies in inverse proportion to output.

Indeed, given any definite magnitude of aggregate productive expenditure, the only way that average unit cost in the economic system can increase is by virtue of aggregate production correspondingly decreasing, for average unit cost in the economic system as a whole is aggregate productive expenditure divided by aggregate output. By the laws of mathematics, with a numerator that is fixed, the only way that a fractional expression can increase is by virtue of a corresponding decrease in the denominator, which in this case is aggregate output. Thus, any government regulation that raises average unit costs in the economic system is accompanied by a corresponding reduction in aggregate output.

The consequence of any lesser overall ability to produce is, of course, a reduced ability to produce capital goods, as well as consumers' goods. More precisely, the effect of all such regulations is to reduce the ratio of output to the capital goods consumed in producing that output, and therefore to make the maintenance proportion unnecessarily high. When placed together with the taxes described a few paragraphs back, the combined effect is a lower relative production of capital goods and a higher maintenance proportion, with a corresponding two-sided reduction in the portion of output available for

new capital formation. Indeed, that portion can be eliminated altogether, and stagnation or outright capital decumulation made to take the place of capital accumulation.

Government budget deficits and social security, like the taxes I have described, also operate to reduce saving and productive expenditure. To the extent the deficits are financed by borrowing from the public (as opposed to the printing of money), they represent a diversion of savings from use as capital to the financing of the government's consumption. To the extent they are financed by the creation of money, they operate to create both additional nominal profits, on which businesses must pay taxes, and to raise the replacement cost of capital assets. Thus, they operate to make it more difficult or even impossible to replace capital assets. And in still other ways, inflation-financed deficits undermine capital formation.⁸⁹ Social security leads people to reduce their provision for the future, in the belief that their needs will be provided for by the government. Meanwhile the government consumes their social security contributions. Thus, in this way too, capital accumulation is undermined.⁹⁰

In the face of such an assault on the foundations of capital formation, it should hardly be surprising that the present-day United States has fallen from its previous position of unchallenged economic eminence. The United States is a country whose economic foundations have been sapped by wave after wave of socialistically motivated assaults on capital formation. In this century, there has been the Progressive Era and the Square Deal, then the New Deal, the Fair Deal, and the Great Society, all bent on fundamentally altering the nature of the American economic system and, unfortunately, succeeding in doing so. Until these policies, and the envy- and resentment-filled mentality on which they are based, are reversed, the United States will continue on its path of decline.

What is required to restore economic progress and rising real wages in the United States is nothing less than radical reductions in government spending, taxation, and government regulation of business. Specifically, what is necessary is to begin phasing out the progressive personal income and inheritance taxes, the corporate income tax, the capital gains tax, the social security system, and the whole of the welfare state, which makes the revenues raised by these destructive taxes appear necessary, and, at the same time, to move toward a gold standard and the end of the arbitrary creation of money. Such a program, coupled with an equally massive reduction in government regulation, would enormously increase not just the incentive and means to save, which would be important enough, but *all* of the incentives to produce and compete. People would work harder and produce more in the knowledge that more of what they earned was theirs to

keep. More new companies would be started and be able to grow rapidly and challenge the established firms, if they could plow back most of their profits. All firms would improve in efficiency if they were free of restrictive regulations. The rate of innovation and technological progress would increase. Thus, along with a sharp rise in the relative production of capital goods, the productivity of capital goods would greatly increase and the maintenance proportion correspondingly decrease. This combination of a higher relative production of capital goods and reduced maintenance proportion would assure a sharply higher rate of capital accumulation. It would thus restore a rising productivity of labor and rising real wages. (And, of course, real wages would increase on the strength of a rise in the demand for labor made possible by the reduction in government spending, taxes, and deficits.) This is clearly the path to the long-term economic recovery of the United States (or any other country). The effect would be to lift the United States out of the stagnation of the last generation and restore it to rapid economic progress—to rapidly rising real wage rates and a rapidly rising general standard of living.

Regrettably, so powerful is the grip of ignorance and envy, that no amount of economic decline by itself seems likely to awaken the present generation of Americans to the fact that they, their twentieth-century political heroes, and their present chosen leaders might in any way be responsible for the decline through the economic policies they support and sustain, and that what is required is the radical reversal of those policies. Following the completion of my economic analysis, the final chapter of this book will attempt to develop a concrete, long-range political-economic program and strategy for achieving the necessary changes.

Happily, a leading implication of the analysis of capital accumulation I have presented here is that it is never too late for such a program. For what I have shown is that while no amount of existing capital goods and prosperity, however great, is a guarantee of the maintenance of those capital goods and prosperity, so too it is possible even for the very poorest of countries to rise, or for a country to resume its rise no matter how great its fall from former prosperity. All that is necessary is that it become more efficient in the use of whatever capital goods it continues to possess, and devote a proportion of them and of its labor to the production of further capital goods that is greater than the maintenance proportion. It is highly unlikely that the economic decline the United States may experience in the coming decades will place it below the level of Japan in 1950. But even if that were the case, it would still be possible for the United States rapidly to reverse the damage and, before too long, to exceed its former peak and go on advancing from there. To do so,

it would simply have to turn once again to the philosophy of economic freedom on which it was built. That would ensure both the necessary efficiency in the use of whatever capital goods existed and a sufficient concentration on the production of further capital goods.

The Nonsacrificial Character of Capital Accumulation Under Capitalism

It should be obvious that the analysis of this chapter implies that capital accumulation under capitalism takes place *nonsacrificially*, and was in the interest of the average wage earner even in the earliest years of the Industrial Revolution. (This, of course, is in sharpest contrast to conditions under socialism, where capital accumulation, if it can be achieved at all, must be achieved at the cost of human life.⁹¹)

Capital accumulation under capitalism was not inaugurated by any temporary fall in the standard of living of the average wage earner. It did not come about as the result of any sudden major rise in the demand for capital goods coming at the expense of a reduction in the demand for labor and thus at the expense of consumption expenditure on the part of wage earners. On the contrary, it was inaugurated by a rise in the economic degree of capitalism, combined with a rise in the efficiency with which existing capital goods were employed. The effect of the higher economic degree of capitalism was *a rise in the demand for labor alongside the rise in the demand for capital goods*. Thus, a higher degree of capital intensiveness in the economic system was achieved as part of a process which raised wage payments relative both to consumption and to total sales revenues in the economic system. In addition, the Industrial Revolution represented the greatest increase in the efficiency of production and in the use of existing capital goods in all of human history. This in turn meant the greatest decrease in the maintenance proportion in all of human history. To this extent, capital accumulation was not the result of any actual reduction in consumption, however temporary, on the part of *anyone*—even businessmen and capitalists. For, to this extent, capital accumulation was made possible out of an increase in production.

In limited circumstances, to be sure, there can be a fall in the demand for labor and rise in the demand for capital goods. Indeed, when Ricardo became aware of this possibility, he mistakenly concluded that his previous views concerning the beneficial effects of machinery were mistaken and “that the opinion entertained by the labouring class, that the employment of machinery is frequently detrimental to their interests, is not founded on prejudice and error, but is conformable to the correct principles of political economy.”⁹² Marx, of course, also assumed that capital accumulation originating in a reduced demand for

labor was necessarily against the interests of the wage earners. It can now be seen that the actual effect of such a change in demand, to whatever extent it occurs, is ultimately to reduce prices to a greater extent than wage rates and thus to raise real wage rates—that, in other words, Ricardo and those who follow him in this have committed the error, so clearly identified by Ricardo himself, of confusing “value” and “riches,” that is, of confusing a reduction in the monetary demand for labor with a decline in the real wealth obtained by wage earners.⁹³ This conclusion can be demonstrated both on the basis of the determination of prices by cost of production and on the basis of the determination of prices by supply and demand.

If the rate of profit remains the same, a reduced demand for labor reduces wage rates, costs of production, and prices all to the same degree. This follows from the fact that the price of every product can be expressed as a sum of wage payments made at the various stages of production, with each such wage payment multiplied by one plus the rate of profit raised to a power corresponding to the time which elapses between the making of the wage payment and the sale of the ultimate consumers’ good.⁹⁴ For example, the price of a loaf of bread can be expressed as the sum of the wages paid per loaf of bread to workers engaged in wheat growing, flour milling, and baking (and all the other stages of production that stand behind the baking of bread), with each such wage payment multiplied by one plus the rate of profit raised to a power corresponding to the time which elapses between the payment of the respective wages and the sale of the loaf of bread. Thus, if the rate of profit remains the same, while wage rates fall, it follows that prices must fall in proportion to the fall in wage rates. However, precisely the fact that the fall in demand for labor and in wage rates is the result of a rise in the demand for capital goods and thus in the relative production of capital goods and hence in the productivity of labor, means that unit costs, and therefore prices, must fall to a greater degree than wage rates. For the corollary of the rise in the productivity of labor is a corresponding reduction in the quantity of labor required to produce a unit of goods. Thus, unit costs of production and prices fall because of the operation both of the fall in demand for labor and the rise in the productivity of labor, while wage rates fall only because of the fall in demand for labor. The net upshot is that this case merely constitutes yet a further confirmation of the proposition that real wages are determined by the productivity of labor.

In terms of demand-and-supply analysis, the reduced demand for labor and enlarged demand for capital goods both reduces the demand for consumers’ goods (inasmuch as the wage earners have equivalently less to spend

for consumers' goods) and, as I will show in Chapter 17, by enlarging the demand for capital goods relative to the demand for consumers' goods, serves to lengthen the "average period of production."⁹⁵ The result is that, once again, the prices of consumers' goods fall in proportion to the fall in demand for labor and wage rates. At the same time, however, the higher productivity of labor, which results from the greater relative production of capital goods, increases the supply of consumers' goods. Thus, prices fall more than wage rates because both prices and wage rates fall in proportion to the fall in the demand for labor, while prices also fall in proportion to the resulting increase in the supply of consumers' goods.

A few further words are required to show why supply-and-demand analysis supports the fact that prices must fall in proportion to wage rates—apart from their further fall in proportion to the increase in the supply of consumers' goods. Strictly speaking, a fall in the demand for labor brought about by a rise in the demand for capital goods must decrease the demand for consumers' goods by a lesser percentage than it decreases the demand for labor. This is the case insofar as the demand for consumers' goods is initially larger than the demand for labor. Thus, for example, if the demand for consumers' goods is initially 500 units of money and the demand for labor is initially 400 units of money, an equal decrease in the demand for labor and consumers' goods of 100 units of money reduces the demand for labor by 25 percent, and the demand for consumers' goods by only 20 percent. Nevertheless, the prices of consumers' goods still tend to fall by 25 percent.

What reconciles the unequal percentage changes in demand with the outcome based on the cost-of-production analysis is, as I have indicated, a lengthening of the average period of production, which necessarily results from the demand for capital goods rising at the expense of the demand for labor and thus, indirectly, at the expense of the demand for consumers' goods. The nature of a lengthening of the average period of production, and its influence on prices in the face of the demand for consumers' goods falling proportionately less than the demand for labor can be understood in terms of the example of twelve-year-old scotch replacing eight-year-old scotch in the market. A 20 percent reduction in expenditure for scotch would easily be capable of being accompanied by a reduction in the price of scotch of 25 percent, indeed, of far more than 25 percent, if twelve-year-old scotch now sold for 20 percent less than eight-year-old scotch used to be sold for. Just so, a lengthening of the average period of production means that in general, goods with a longer average time span in their production come to take the place in the market of goods with a shorter average time span in their production. In

this way, a lesser percentage fall in demand for consumers' goods is capable of being accompanied by price reductions of a greater percentage than itself.

To place this analysis in the actual context of the rise in the economic degree of capitalism, what it means is that the demand for labor may recede somewhat from the peak to which a higher economic degree of capitalism has raised it. But then, of course, on the basis of the more rapid rate of capital accumulation and increase in the productivity of labor that is brought about by the greater relative production of capital goods and higher degree of capital intensiveness, real wages quickly recover from any temporary setback and go on further and further surpassing any previous peak. And, of course, in the process, the demand for labor, and with it average money wage rates, would also almost certainly be rising, as the result of the increase in the quantity of money that would almost inevitably accompany increasing production under a commodity money standard.

To understand just how rapidly any such temporary decline in real wages could be made good, it is only necessary to realize that over a 10 year period, a 2 percent addition to the annual rate of economic progress raises real wages by approximately 22 percent and that a 3 percent addition raises them by approximately 34 percent. (At the approximately 6 percent annual rate of economic progress that has taken place in Japan and other East Asian countries over the last several decades, the rise in real wages over the course of a decade is 79 percent. Over the course of three decades, it is over 579 percent.)

Indeed, it is virtually impossible that the inauguration or intensification of capital accumulation and economic progress in a capitalist country could ever result in a reduction in average real wages that would not be made good very quickly. This is because the basic effect of a higher economic degree of capitalism is to raise the demand for labor, as well as the demand for capital goods, relative to consumption and total sales revenues in the economic system. At the same time, the higher economic degree of capitalism is itself part of an even wider process which has as another major effect a rise in the productivity of capital goods and corresponding fall in the maintenance proportion.

The conclusion concerning the very limited extent and temporary nature of any fall in real wages as the result of capital accumulation and economic progress appears all the stronger, when one takes into account the fact that any rise in demand for capital goods at the expense of the demand for labor that might take place, despite the fundamental background of a rise in the demand for both, would not take place suddenly and dramatically, all at once, but only gradually, over a period

of years. Thus each succeeding year over which the process occurred would benefit from the operation of forces already in place that were working to bring about a rise in real wages. Indeed, in the case of the Industrial Revolution in England, the process of capital intensification and the corresponding rise in the ratio of the value of accumulated capital to wage payments, appears to have taken place and been largely completed in the century and a half or more *prior* to 1775—the year usually taken as marking the beginning of the Industrial Revolution. This was manifested in the fall in the rate of interest on long-term government bonds in England to 3 percent as early as 1757.⁹⁶ Thus, under no circumstances could the Industrial Revolution have been responsible for any fall, however temporary, in the average worker's real wages in England.

What did hold down the standard of living of the average English worker at the time was twenty-five years of almost uninterrupted war with France between 1790 and 1815. The taxes and loans to pay for the war deprived business firms of the ability both to pay wages and to buy capital goods and thereby worked against both the so-called wage share of national income and the productivity of labor. Wartime inflation and the subsequently resulting postwar deflation and depression further substantially contributed to the undermining of capital accumulation and the rise in real wages.⁹⁷

Only in a socialist country, such as Soviet Russia, with its gross inefficiencies and impossibly high maintenance proportion, can a process of capital accumulation or, more accurately, alleged capital accumulation, not be accompanied by rising real wage rates starting at virtually the same time.⁹⁸

On the basis of the foregoing, it is necessary to disagree completely with such alleged defenses of capitalism as the following statement of de Jouvenel's: "[O]ne may ask whether the 'hard times' so bitterly evoked, and for which capitalism is arraigned, were a specific feature of capitalist development or are an aspect of a rapid industrial development (without outside help) to be found as well under another social system. Does the Magnitogorsk of the 1930s compare so favorably with the Manchester of the 1830s?"⁹⁹ In this passage, de Jouvenel displays the grossest ignorance of the actual nature of capitalism's economic development, equates nineteenth-century capitalist Great Britain with twentieth-century Communist Russia, and implies that socialism is capable on its own of achieving capital accumulation. It is difficult to imagine compressing a larger number of more profound errors into such a small number of words.¹⁰⁰

While capitalism and the Industrial Revolution operated from the very first to raise the standard of living of the average worker, even they could not succeed in

raising the standard of living of workers who refused to abandon occupations made obsolete by the process of improvement, as was the case with the English handloom weavers, for example. As the progressive application of machinery driven by man-made power drove the price of cloth ever lower and enabled the average wage earner in Britain, and in all the countries to which Britain exported cloth, to enjoy rising real wages insofar as they could now afford to buy more and better cloth and clothing, the handloom weavers, in blind obstinacy, carried on in the weaving of cloth by hand. As a result, for them, the falling price of cloth meant falling earnings.

Such occurrences were not the fault of capitalism and the Industrial Revolution, but of the refusal of workers to change occupations (and, of course, of any legal factors that may have prevented them from changing their occupations.) If such workers had changed their occupations, and thus reestablished their capacity to earn an income, the effect would have been that they, along with everyone else, would have benefitted even from the very improvements that initially had cost them their jobs, as did American horsebreeders and blacksmiths as the result of the coming of the automobile. The case of the handloom weavers, and all other such workers, is the same in principle as that of the potato growers, which I presented in connection with the exposition of Say's Law in the last chapter.¹⁰¹ In the absence of government intervention, there is absolutely no need for it to have any other outcome than a beneficial one for all concerned. Capitalism should not be blamed either for the existence of government intervention that prevents workers from making rational choices concerning their occupation, or, in the absence of government intervention, for the refusal of workers to make rational choices concerning their occupation.

Appendix to Section 3: An Analytical Refinement Concerning the Rate of Economic Progress

The extremely rapid rate of reciprocating capital accumulation and increases in production present in Figure 14–5 is the result specifically of the assumption that it is possible to have a progressing economy in which all capital goods are productively consumed in a single year. In reality, of course, this is not possible. This is because there are numerous capital goods, such as virtually all major factories and office buildings, whose construction time is significantly longer than a year. Construction times for railroads, bridges, tunnels, highways, dams, and so forth are typically even longer than those for factories and office buildings. Also, given the great expense of producing these various types of capital goods, and most types of machinery as well, it is essential that they be used for periods substantially longer than a year.

Thus, in reality, the accumulated stock of capital goods in existence at the beginning of any given year substantially exceeds the portion of that stock which is productively consumed within the year.

These facts can be allowed for in our analysis by introducing the assumption that while $1K$ of the opening stock of capital goods in any given year is productively consumed in producing an output lying between the extremes of $2K$, $0C$ and $0K$, $2C$, there must be an accumulated stock of capital goods in existence at the beginning of the year that is, for example, five times larger, namely, $5K$. Under this assumption, the 20 percent increase in the production of capital goods in *Year 1* of Figure 14–5 would not constitute a 20 percent increase in the accumulated stock of capital goods available at the start of *Year 2*, but only a 4 percent increase, namely, an increase in the ratio of $5.2K: 5K$.

Furthermore, if the addition to the supply of capital goods were all in the form of work in progress, such as construction in progress, the larger supply of capital goods in existence at the beginning of *Year 2* would not serve to make the output of *Year 2* larger than that of *Year 1*. The increase in output would have to await the completion of projects extending beyond a year.

To keep matters as simple as possible with this more complicated context, let us momentarily assume that no increase in production can take place until 5 years have elapsed, by which time the 20 percent larger relative production of capital goods in each year will have resulted in increasing the accumulated stock of capital goods from $5K$ to $6K$. Under this assumption, the 20 percent increase in the overall ability to produce that is made possible by a 20 percent increase in the supply of capital goods will not take place until *Year 6*, rather than *Year 2*. And then that 20 percent increase in the ability to produce, assuming that it is devoted 60 percent to the production of capital goods, will result in an increase in the accumulated stock of capital goods to $6.24K$ at the start of *Year 7*. (This is because $1.44K$ of capital goods are now produced, while $1.2K$ of the $6K$ are productively consumed.)

Assuming once more that the additional supply of capital goods is all in the form of work in progress and that 5 years of such capital accumulation must go by before production can increase in proportion to the larger stock of capital goods, it will not be until *Year 11* that the overall ability to produce increases by a second 20 percent.

In other words, while the fundamental principle is still present that increases in the supply of capital goods increase the ability to produce capital goods and thereby constitute the basis for continuing capital accumulation, the operation of that principle is slowed down by the need to build up an additional capital stock over a period of

years. The regularly recurring 20 percent increases first in the stock of capital goods, then in production, and then again in the stock of capital goods because of the preceding increase in the ability to produce, now take place over 5-year intervals instead of from year to year. The effect of this, of course, is to reduce the annualized rate of economic progress from 20 percent to 4 percent.

To carry the analysis yet another step closer to the details of reality, we must recognize that the greater part of the increases in the supply of capital goods that occur in less than 5-year intervals serve to increase the overall ability to produce also in less than 5-year intervals. Thus, perhaps in *Year 3*, for example, when the supply of capital goods has reached $5.4K$, the overall ability to produce might now be increased by a few percent in comparison with that of *Year 1*. And it would almost certainly further increase by an additional few percent in *Years 4* and *5*. (To the extent such increases in production take place prior to *Year 6* rather than all being concentrated in *Year 6*, the increase in production in *Year 6* would, of course, be correspondingly less than 20 percent.) The average annual rate of increase in the supply of accumulated capital and in production would still be on the order of 4 percent rather than 20 percent, though somewhat more rapid than in the case in which the increase in production occurs only in 5-year intervals, because now there is compounding over shorter intervals of time.

This establishes the basic pattern of the relationship between my simplifying assumptions and the complex conditions of actual reality.

4. The Productivity Theory of Wages and the Interpretation of Modern Economic History

Now that the productivity of labor and thus real wages have been shown to be determined by capital accumulation, which in turn has been shown to rest on a foundation of respect for property rights and individual freedom—and ultimately, at the deepest level, on the influence of reason in a country's culture—it is possible to see that the productivity theory of wages provides a full alternative to the Marxian interpretation of modern economic history. According to the Marxian interpretation of economic history, which is generally taken for granted, the standard of living of the average worker in the nineteenth century was low because the capitalists had unchecked freedom to exploit him.

The Cause of Low Wages and Poor Working Conditions in the Past

The productivity theory of wages explains the low real wages and low standard of living of the nineteenth cen-

ture not on the basis of any “exploitation of labor” by the capitalists, but on the basis of a *low productivity of labor*, inherited from centuries of feudalism, which low productivity of labor the activities of the businessmen and capitalists immediately began to raise.

To understand how low the productivity of labor was in the past, all one has to do is to look around at the goods commonly available today in the United States and other Western countries, and consider just how recent was their introduction. As we go back in time, the automobiles, airplanes, air-conditioners, computers, telephones, television sets, tape recorders, radios, phonographs, motion pictures, refrigerators, freezers, electric lights, antibiotics, antiseptics, and anesthetics all disappear. So do motor trucks, tractors and harvesters, electric power plants, steamships, and railroads. So do electric motors, steam engines, and power tools and power-driven machinery of every description. Not only do so many of the goods we take for granted simply disappear, but whatever goods remain must be produced laboriously, by hand—by human muscle power aided only by animals and, at best, by the power of wind and falling water.

In the absence of all of these goods and of all the modern methods of production, it should certainly not come as a surprise that the average standard of living was miserably low. By modern standards, the standard of living even of the world’s richest people of two hundred years ago, or even just one hundred years ago, was extremely low. It was simply not possible for people to have goods that did not exist. And of the goods that did exist, it was simply not possible for most people to have very many of them, when, for example, each piece of wood used to build a house had to be sawed by hand and everything else that entered into the construction or furnishing of a house had to be made by hand; when every piece of clothing that a person wore, and every piece of food that he ate, had to be produced in the same way, that is, with the aid of virtually no power-driven machinery of any kind.

The low productivity of labor of earlier generations provides a full and sufficient explanation of the low standard of living of those generations. It also explains the long hours of work, child labor, and the bad working conditions. Long hours and child labor existed because the low productivity of labor—the low output per hour of labor—meant that a minimal standard of living could be achieved only by the performance of a correspondingly large number of hours of labor, to compensate. People worked long hours because the low productivity of labor rendered the output of a shorter working day, of the length we are accustomed to think of as desirable, inadequate to provide the minimum supply of goods people considered it necessary to have. Children worked

alongside of adults because the low productivity of labor rendered even the long hours of the adults insufficient to produce the minimum supply of goods people considered it necessary to have.

Working conditions were very poor in large part because the low productivity of labor meant that the means of making them better simply did not exist. For example, it was absolutely impossible to give workers the benefit of electric light or air conditioning or modern plumbing on the job, when such things had not even been invented. For the rest, working conditions were very poor because the low productivity of labor made it impossible to improve them except at the expense of driving the workers’ low standard of living still lower.

In this connection, it must be understood that there are two types of improvements in working conditions among those that are possible within any given existing state of technology: namely, those improvements which pay for themselves, through making production more efficient, and those which do not pay for themselves. Improvements in working conditions of the kind which pay for themselves, through bringing about sufficient increases in efficiency, are adopted by employers not only voluntarily, but with exactly the same eagerness as leads them to adopt any other improvement in efficiency, such as better machinery.

Improvements in working conditions of the kind which do not pay for themselves represent an increase in the cost of employing workers. If such improvements are not to be equivalent in their effects to a forced increase in nominal wages—that is, to cause unemployment, higher prices, and a burden of supporting the unemployed—they must be accompanied by an equivalent reduction in that part of the cost of employing labor which the worker receives directly for himself, i.e., his take-home wages. In either case, such improvements in working conditions are at the expense of the average worker’s standard of living off the job. In the latter case, his take-home wages are reduced. In the former case, if he is lucky enough to keep his job, the prices he must pay are increased, and he must help to support those who become unemployed as the result of the rise in employment costs. If his standard of living is already very low, then it follows that improvements in working conditions that reduce it still further are likely to be *against* the actual self-interests of the workers and to be rejected by them in the labor market. What this means is that when asked to choose between jobs offering better on-the-job conditions but correspondingly lower take-home pay, and jobs offering poorer on-the-job conditions but correspondingly higher take-home pay, the workers will choose the jobs offering the poorer on-the-job conditions and higher take-home pay. To this extent, working conditions are poor because

in the prevailing conditions of a low productivity of labor, the wage earners judge that they cannot afford to have them any better.

How Real Wages Rose and the Standard of Living Improved

The productivity theory of wages explains how all aspects of the workers' conditions improved. The starting point was a growing degree of rationality and a growing respect for property rights in society. These resulted in the achievement of a sufficiently high relative production of capital goods, the discovery and adoption of technological advances, and a general improvement in the efficiency of use of capital goods, all of which brought about capital accumulation and a rising productivity of labor. At the same time, of course, the sufficiently higher relative production of capital goods was accompanied by a rise in the demand for labor relative to the demand for consumers' goods—both changes being the reflection of a higher economic degree of capitalism. This, too, contributed to a rise in real wages, even if on an essentially nonrepeatable basis.

The direct effect of a rising productivity of labor was a rise in the average worker's real wages. As people's real wages rose, a further effect was that they could afford to reduce their hours of work. For as the real earnings from jobs requiring the accustomed number of hours rose, so did the real earnings from jobs requiring fewer than the accustomed number of hours. For example, in the earliest years of the Industrial Revolution, the productivity of labor was still so low that many people needed to work eighty hours a week in order to earn enough to support a family. A generation or two later, a doubled productivity of labor not only doubled the real earnings that could be obtained from a job of eighty hours a week, but, at the same time, made it possible to obtain substantially larger real earnings from jobs requiring seventy or sixty hours a week than it had originally been possible to obtain from jobs requiring eighty hours a week. Although jobs requiring eighty hours a week still offered more than jobs requiring seventy or sixty hours a week, the jobs requiring seventy or sixty hours a week now offered *enough* for most people to be able to afford to take them.

As more and more workers could afford the relatively lower earnings from jobs with shorter hours, and came to desire such jobs, *the competition of the labor market operated to reduce the number of hours in the average work week*. Whenever employers had to compete for labor, the offer of shorter hours was a powerful means of recruiting the labor they sought. And as the shorter week became more and more widespread, it became necessary for those employers who had not yet offered it, to do so, in order to retain the labor they already had.

In addition, another powerful competitive factor favored the adoption of a shorter work week. Namely, the desire of workers for a shorter week operated to make it *more economical* to employers to offer a shorter week. This was because to the extent that workers wanted a shorter week, they became willing to accept jobs offering shorter hours at wage rates that were lower *more than in proportion to the shorter hours*. For example, to the extent that they strongly desired a sixty-hour week, say, in place of an eighty-hour week, they became willing to accept jobs requiring a sixty-hour week at wages less than three-fourths of the wages of jobs requiring an eighty-hour week. This meant that an employer who offered the shorter week would have correspondingly lower unit costs of production than employers who offered the longer week. This represented a cost reduction over and above any reduction that could be achieved by virtue of the workers' being able to produce more per hour with a shorter week, which in itself was no doubt significant.

There should be nothing surprising or disturbing in any of this. The statement that the desire of workers for shorter hours leads to a discount in the wage rates for shorter hours is only another way of saying that the labor market tends to impose *premium wage rates* for jobs requiring hours that the market regards as excessive. Just as today premium rates for overtime imposed by the government discourage the use of overtime, so the premium rates that the market comes to generate for jobs with relatively long hours discourage the offer of such jobs. And the more strongly the workers prefer to work shorter hours, the greater are the relative discounts in the wage rates that can be offered in connection with jobs requiring shorter hours, and the greater are the relative premiums in the wage rates that must be offered in connection with jobs requiring longer hours. Thus, to the extent that the workers come to be able to afford and to desire shorter hours, the greater is the encouragement to the offer of shorter hours.

This, not legislation, is the actual process by which the hours of work have been reduced over the span of the last two hundred years—first, from eighty hours a week to seventy or sixty hours a week, then to fifty hours a week, and then to forty hours a week. Future generations of capitalism, with further doublings and redoublings of the productivity of labor, could well see real wages raised to such a point that people would be able to earn vastly more in thirty, twenty, or even ten hours a week than they now can earn in forty hours a week, with the result that the average person might someday have a real income substantially higher than that of a present-day physician, say, while working the hours of a present-day college professor.

The rise in the productivity of labor was also responsible for the progressive reduction in child labor. For as people's real wages rose, another effect was that they could afford to keep their children home longer. Thus, child labor diminished—not as the result of legislation, but as the result of rising real wages brought about by a rising productivity of labor.

Although the connection just made is actually very simple, it cannot receive enough stress or elaboration. With the exception of orphan children, those who decided whether or not children would work, and, if so, to what extent, were the children's parents. As soon as parents began to decide that they no longer needed as much help from their children, because their own real wages were now higher, they began to keep their children home longer, and thus to reduce the amount of child labor.

Thus, as the productivity of labor and the real wages of the parents rose, the age at which children went to work steadily increased. In the preindustrial seventeenth century, humanitarians contemplated ways in which orphan children of the age of three might be taught some simple skill, so that they might be enabled to contribute to their own support and thereby survive, in the face of the very meager charitable contributions that were all that the extremely poor society of the time could provide. In the earliest years of the Industrial Revolution, there were children who went to work at the age five or six. In the early nineteenth century, the starting age rose to seven or eight; later in the century, to nine or ten. By the beginning of the twentieth century, it was more often eleven or twelve. Today, it is typically not until the completion of a high-school or college education, and in a significant number of cases, a postgraduate education.

In addition, the rise in the productivity of labor was responsible for the improvement in working conditions that has taken place over the last two hundred years. As already indicated, one aspect of the rising productivity of labor was the very coming into being of goods that could constitute an improvement in working conditions in the first place, such as electric light and air conditioning. Another aspect was that as the productivity of labor rose in the production of goods capable of improving working conditions, and reduced their cost, the instances in which improvements in working conditions paid for themselves through greater efficiency increased. This was because any given improvement in efficiency was now weighed against a reduced cost of achieving it. A further aspect of the rise in the productivity of labor was that the higher real wages it achieved enabled workers more and more to afford to take jobs offering relatively better working conditions at the cost of relatively lower take-home pay. This was because jobs with relatively

lower take-home pay now offered far more than had jobs geared to the utmost in take-home pay in the past.

Thus, working conditions improved by virtue of the same process of competition in the labor market as reduced the hours of work. As workers came to be increasingly able to afford better conditions at the price of lower take-home pay, employers who offered the combination of better conditions together with take-home pay lower by enough to offset their cost, gained an increasingly powerful competitive advantage in recruiting workers. For as real wages rose because of the rising productivity of labor, the marginal utility that wage earners attached to the specific amount of real income required to achieve a given improvement in working conditions progressively fell. Once it fell below their rising valuation of the better working conditions, the effect was a growing relative discount in the wages of jobs with better working conditions, and a growing relative premium in the wages of jobs with poorer working conditions, which premiums and discounts more and more exceeded the cost of providing the improvements. Thus, the offer of better conditions was made more and more economical to employers. In the present-day United States, for example, the premium in take-home wages that would have to be paid to induce most workers to work in a factory without modern plumbing so far exceeds the cost of having such plumbing as to make its absence almost unthinkable. Or, to say the same thing in different words, the offer of an amenity such as modern plumbing makes possible to employers a saving in take-home wages that far outweighs its cost. The same principles, of course, apply to the presence or absence of such things as air-conditioning, cafeterias, recreational facilities, child-care centers, and so on, and to job safety, which is an important aspect of working conditions.

It needs to be pointed out that government policies promoting inflation and credit expansion, and thus the boom-bust cycle, especially when compounded by policies that interfere with the fall in money wage rates in the depression phase, can impede the market's ability to shorten hours and improve working conditions. To the extent that a situation is created in which money wage rates need to fall to reestablish full employment, and have not yet done so, or are prevented from doing so, reductions in labor cost may instead be achieved by a lengthening of hours in the face of the same weekly wages and at the expense of working conditions. In a free labor market, the workers would choose a fall in money wage rates as the means of reducing labor costs, and, as I have shown, would end up with no reduction in their real wages, because of the resulting fall in prices.¹⁰² But to the extent that that is made impossible, they become willing to accept the equivalent of substantially lower

real wages in the form of longer hours and poorer conditions rather than become unemployed and earn no wages. This constitutes a further argument against inflation and credit expansion and government interference with wage rates.

It is appropriate to consider here the fable of the company towns. Though I have not been able to find it in the writings of Marx himself, the doctrine of company towns claims that, not content with the payment of outrageously low wages, the capitalist exploiters also frequently built company towns for the purpose of charging the workers outrageously high prices. It is difficult to understand why the capitalists would go to the trouble of investing substantial sums in the construction of whole towns in order to squeeze extra profits from the workers if they have arbitrary power over wage rates, as the Marxists believe. Because if they really did have such power over wage rates, it would be far simpler for the capitalists just to cut wages by an amount equal to the profit they allegedly make by virtue of owning the company town. This would give them the same amount of profit or “surplus-value” and a substantially higher rate of profit, because they would avoid having to tie up the substantial amount of capital needed to build and operate a town.

Of course, the capitalists do not have arbitrary power over wage rates, and to induce workers to work for them they must offer the workers a combination of wage rates, working conditions, and—as far as competition with capitalists in other areas goes—living conditions (including access to housing and retail stores) that is superior to any other such combination that the workers believe is available to them. If they do not, they will lose their workers. The obvious reason that the capitalists sometimes built company towns was that doing so enabled them to offer a combination of these elements that was of greater value to the workers than if the same amount of capital had been invested in the payment of wages exclusively. In the case of companies operating in relatively isolated areas, which offer few amenities and little of value to spend money on, the payment of the maximum possible wage rates is of less value to the workers than the offer of a combination of lower wage rates together with such amenities as housing and stores. This is why company towns were built. This is why they are still occasionally built today. For example, American companies operating in places like Saudi Arabia or the North Slope of Alaska provide the equivalent of company towns. Such towns represent a major positive value to the workers and are essential for attracting sufficient workers.

The fact that prices in the stores of a company town

may often be higher than prices in better-located, more-populous areas is indicative not of unusual profits being made in such stores, but of the high costs of supplying such remote and isolated locations. If high profits were the explanation, there would soon be other suppliers in the vicinity. The fact that occasionally a worker might become excessively indebted to the stores in a company town is of no more significance than the fact that people can and do become excessively indebted without company towns. The complaints against company towns deserve no more credence than any other aspect of the exploitation theory.

5. A Rise in the Productivity of Labor as the Only Possible Cause of a Sustained, Significant Rise in Real Wages

It needs to be understood not only that the rise in the productivity of labor has been the cause of the rise in real wages and the average wage earner’s standard of living over the last two hundred years, but also that the rise in the productivity of labor is the *only possible* such cause. For let us consider the alternatives.

Any rise in *money wage rates*, by itself, is inherently incapable of raising real wage rates (with one relatively minor exception to be explained shortly). This becomes clear when we examine the possible sources of a rise in money wage rates.

The Futility of Raising Money Wage Rates by Means of an Increase in the Quantity of Money or Decrease in the Supply of Labor

A rise in money wage rates can be achieved either by an increase in the demand for labor or by a decrease in the supply of labor. The most obvious source of a rise in the demand for labor is an increase in the quantity of money. But, as we have already seen, while increases in the quantity of money operate to raise the demand for labor and thus money wage rates, they also operate at the same time to raise the demand for consumers’ goods and thus the prices of consumers’ goods, and to the same extent. Thus, the rise in money wage rates brought about by a larger quantity of money does not constitute a rise in real wages. Indeed, when increases in the quantity of money exceed the relatively modest rate of increase in the supply of precious metals, they constitute inflation and begin to produce all of the problems associated with inflation. Among these problems is a slowing down of capital accumulation or outright capital decumulation, as will be shown in Chapter 19 of this book. This, of course, holds down the rise in the productivity of labor and real wages, or actually causes them to decline.¹⁰³

A rise in money wage rates brought about by a reduc-

tion in the supply of labor also does not represent any rise in real wages, but the contrary. We have already seen that this is the case when the supply reduction represents nothing more than forced unemployment for the purpose of achieving or maintaining a higher level of money wage rates. For then, there is the problem of fewer workers employed producing fewer consumers' goods, which must be sold at correspondingly higher prices, and the further problem of having to support the unemployed. By the same token, a long-term reduction in the size of the population, and thus in the number of people able and willing to work, would raise money wage rates, but it would also reduce the extent of the division of labor, and thus operate to reduce the productivity of labor and therefore to raise prices even more than wage rates.¹⁰⁴

The demand for labor could rise by virtue of a decrease in the desire of people to hold money, which would manifest itself in a rise in the so-called velocity of circulation of money—that is, in a more rapid rate of spending of any given quantity of money. However, as I have shown, such a phenomenon, when significant, is itself the result of rapid increases in the quantity of money. Moreover, like any increase in the quantity of money, it tends to raise prices at least to the same extent as it tends to raise wages.¹⁰⁵

The Futility of a Rise in the Demand for Labor Coming at the Expense of the Demand for Capital Goods

It is conceivable that the demand for labor could rise without either an increase in the quantity of money or a decrease in the desire to own money. It could rise by virtue of a drop in the demand for capital goods. While this would raise nominal wage rates, it would reduce real wage rates, for it would raise prices by more than wages. This case is simply the converse of the case of a fall in the demand for labor and rise in the demand for capital goods, which I have already considered.¹⁰⁶

Thus, in this case, the rise in demand for labor would raise wage rates, unit costs, and prices to the same extent, and the accompanying reduction in the relative production of capital goods and productivity of labor would raise unit costs and prices beyond the rise in wage rates. In terms of supply-and-demand analysis, the rise in demand for labor would result in a virtually equivalent rise in the magnitude of demand for consumers' goods, as the wage earners consumed their additional incomes. This, together with the shortening in the average period of production that is entailed in the rise in the demand for consumers' goods relative to the demand for capital goods, would raise the prices of consumers' goods in proportion to the rise in wage rates. The reduction in the productivity of labor and thus in the supply of consumers'

goods would raise prices beyond the rise in wage rates.

Indeed, because of the accompanying reduction in the ongoing *rate* of capital accumulation, and thus the compounding effect on the productivity of labor, the rise in prices relative to wages, and thus the fall in real wages, would become greater and greater with the passage of time.

Of course, it is not necessary that the supply of consumers' goods fall in comparison with what it was in the past, as the result of the decline in the demand for capital goods. The fall could take the form of the increase in the supply of consumers' goods being less than it otherwise would have been. This as a minimum must be the effect of a rise in the demand for labor coming at the expense of the demand for capital goods. In either event, in every year in which the relative demand for capital goods remained lower in order to make possible a higher relative demand for labor and consumers' goods, the reduction in the actual or potential supply of consumers' goods would become greater. The result of this would be that the rise in prices relative to wages, and the consequent reduction in real wages, would become greater, at least in comparison with what they otherwise would have been.

The present discussion should not be taken to imply that the demand for labor should never rise at the expense of the demand for capital goods or that it is always desirable for the demand for capital goods to rise at the expense of the demand for labor. In a free market, the demand for labor could rise at the expense of the demand for capital goods if the consumers decided they preferred a larger quantity of goods whose production entailed a relatively greater amount of wage payments and smaller expenditures for capital goods at the expense of goods of the opposite description. Such a case would not represent a fall in real wages, but a rise in comparison with the real wages that would exist if the change in consumer demand were not met and thus output was wasted in the form of goods consumers wanted less. A fall in real wages is entailed only insofar as the demand for labor is increased at the expense of the demand for capital goods as the result of government or labor-union coercion.

Moreover, it is important to realize that when a rise in the demand for capital goods at the expense of the demand for labor can serve to raise the productivity of labor (which, of course, is the typical case), there is always the question of by how much and starting at what point in the future. Here both the law of diminishing returns and the height of the rate of profit and interest play a decisive role in limiting the degree of capital intensiveness in the economic system and thus in limiting the demand for capital goods relative to the demand for labor.¹⁰⁷ The essential point of this discussion, however,

is that forced increases in the demand for labor coming at the expense of the demand for capital goods reduce real wages.

The Futility of Raising the Demand for Labor by Means of Taxation

The demand for labor, and thus nominal wage rates, might be increased in still another way. The government could levy taxes that individuals paid with funds they otherwise would have used to purchase consumers' goods. The government could then expend these taxes in the expansion of its own payroll, with the effect of equivalently increasing the economy-wide, aggregate demand for labor. While those who had to pay the taxes would consume less by the amount of the taxes, the recipients of the government's additional wage payments would consume more by the amount of the taxes. Thus the total demand for consumers' goods in the economic system would remain the same, with the government's employees enabled to consume in the place of the taxpayers. Only the aggregate demand for labor would change: it would increase.

If the government's additional demand for labor came at a time of full employment, the effect would be an increase in money wage rates on a pretax basis. If it came at a time of unemployment, the effect could be an increase in overall employment in the economic system.

Essentially this case led Ricardo to call into question his previous convictions about the economic ill-effects of war and government spending. In the same chapter in which he commits his previously discussed error—of arguing that a rise in the demand for capital goods that takes place at the expense of the demand for labor is against the interest of the average wage earner—he also argues that the rise in the demand for labor in the present case is to the interest of wage earners. He writes:

Independently of the consideration of the discovery and use of machinery, to which our attention has been just directed, the labouring class have no small interest in the manner in which the net income of the country is expended, although it should, in all cases, be expended for the gratification and enjoyments of those who are fairly entitled to it.

If a landlord, or a capitalist, expends his revenue in the manner of an ancient baron, in the support of a great number of retainers, or menial servants, he will give employment to much more labour than if he expended it on fine clothes or costly furniture, on carriages, on horses, or in the purchase of any other luxuries.

In both cases the net revenue would be the same, and so would be the gross revenue, but the former would be realized in different commodities. If my revenue were 10,000*l.*, the same quantity nearly of productive labour would be employed whether I realized it in fine clothes and

costly furniture, etc., etc., or in a quantity of food and clothing of the same value. If, however, I realised my revenue in the first set of commodities, no more labour would be *consequently* employed: I should enjoy my furniture and my clothes, and there would be an end of them; but if I realised my revenue in food and clothing and my desire was to employ menial servants, all those whom I could so employ with my revenue of 10,000*l.*, or with the food and clothing which it would purchase, would be to be added to the former demand for labourers, and this addition would take place only because I chose this mode of expending my revenue. As the labourers, then, are interested in the demand for labour, they must naturally desire that as much of the revenue as possible should be diverted from expenditure on luxuries to be expended in the support of menial servants.

And then, very significantly, Ricardo adds:

In the same manner, a country engaged in war, and which is under the necessity of maintaining large fleets and armies, employs a great many more men than will be employed when the war terminates, and the annual expenses which it brings with it cease.¹⁰⁸

Here again, in assuming, irrespective of context, that the wage earners are always "interested in the demand for labour," Ricardo commits the error he himself warned against, namely, confusing "value" and "riches," or money income and real wealth.¹⁰⁹ Even in the very strongest case for Ricardo, namely, that capitalists and landlords voluntarily decide to spend less in purchasing consumers' goods and equivalently more in employing consumers' labor—i.e., labor employed not for the purpose of making subsequent sales (which is necessarily the kind of labor demanded when "a landlord, or a capitalist, expends his revenue in the manner of an ancient baron, in the support of a great number of retainers, or menial servants")—there is no gain to wage earners as a class, and almost certainly a significant loss.¹¹⁰

This is because the effect of an increase in demand for labor in the form of an increment of demand for consumers' labor is correspondingly to decrease the proportion of the supply of labor employed as *producers' labor*, that is, the proportion employed by business firms, for producing products to be sold. This is true even in the case of unemployment, inasmuch as any unemployed workers who end up becoming employed as consumers' labor could have become employed as producers' labor—at least if money wage rates were free to fall. Since all producers' labor is employed directly or indirectly in the ultimate production of consumers' goods, the effect of this reduction in the proportion of the supply of labor employed as producers' labor is correspondingly to reduce the production and supply of consumers' goods and thereby to raise their prices in full proportion to the additional demand for labor and any increase in money

wage rates that is present in this case. The following example, based on our formulas for the wage and price level, will make this point clear.

I assume that initially the demand for labor in the economic system is 400 monetary units, consisting entirely of a demand for producers' labor. Now, because capitalists and landlords change their pattern of consumption to favor the purchase of consumers' labor rather than consumers' goods, a demand for consumers' labor emerges equal to 100 monetary units. Thus, the total demand for labor in the economic system rises to 500 monetary units, an increase of 25 percent. The effect of this is that if the economic system already enjoyed full employment, the average wage rate in the economic system would also be increased by 25 percent in comparison with its initial level, in accordance with the rise in the aggregate demand for labor in the ratio of 500 to 400. Indeed, whether the economic system already had full employment or not, the average level of money wage rates at which full employment can now exist is 25 percent higher than it would otherwise have been. That is, wage rates can now be 25 percent higher than the level to which they otherwise might have had to fall to achieve full employment.

Nevertheless, no one can gain from such a rise in the demand for labor and in wage rates. The reason is that one-fifth of the labor of the economic system is now employed as consumers' labor, which leaves only four-fifths to be employed as producers' labor. This is the new pattern of employment, because the 100 monetary units of demand for consumers' labor is one-fifth of the now larger total demand for labor of 500 monetary units. By the same token, the 400 monetary units of demand for producers' labor, which used to constitute the entire demand for labor, now constitutes only four-fifths of the demand for labor and thus employs only four-fifths of the labor of the economic system.

Given a constant productivity of labor, four-fifths of the supply of labor working as producers' labor produces only four-fifths the output of consumers' goods. In the face of an unchanged aggregate demand for consumers' goods—which, as we have seen is the case here—four-fifths of the supply of consumers' goods results in prices of consumers' goods that are five-fourths of what they used to be. Thus, in this case, *prices rise just as much as wages*. That is, both rise in the ratio of 5 to 4.

They do so because, as I say, to precisely the same extent that wages are increased by the additional aggregate demand for labor that is constituted by the additional demand for consumers' labor, a corresponding proportion of the labor force is bid away from employment as producers' labor. The result of this is that the production and supply of consumers' goods ultimately falls in in-

verse proportion to such rise in the demand for labor, and, as a result, the prices of consumers' goods rise in direct proportion to it. The rise in prices here can, of course, also be understood on the basis of a rise in the costs of production that is brought about by the additional demand for labor and rise in wage rates. Other things being equal, higher wage rates cause correspondingly higher costs of production and thus, given the rate of profit, correspondingly higher prices of consumers' goods.

To grasp the supply and demand aspects of the case algebraically, all we need do is state the aggregate demand for labor D_L as the sum of the wages paid by business plus the wages paid by consumers, that is, as the sum of the demands for producers' labor and consumers' labor. Thus, where w_b is the wages paid by business, that is, the demand for producers' labor, and w_c is the wages paid by consumers, that is, the demand for consumers' labor,

$$D_L = w_b + w_c .$$

The rise in the aggregate demand for labor and in wage rates is in the ratio of $\frac{w_b + w_c}{w_b}$. At the same time, the fall in the proportion of the supply of labor employed by business is in the inverse ratio $\frac{w_b}{w_b + w_c}$. Given the same productivity of labor, this last ratio is also the measure of the reduction in the supply of consumers' goods produced, which, accordingly, must be expressed as

$$\frac{w_b}{w_b + w_c} \times S_c .$$

Inasmuch as the general consumer price level P is equal to $\frac{D_C}{S_C}$, when this reduced supply of consumers' goods is divided into the demand for consumers' goods, D_C , what we see is that

$$\frac{D_C}{\frac{w_b}{w_b + w_c} \times S_c} = \frac{w_b + w_c}{w_b} \times P ,$$

which last expression shows that prices rise to precisely the same extent as wage rates.

Thus far, I have assumed that the productivity of labor remains the same. The fact is that the productivity of labor will almost certainly decrease, thereby bringing about a rise in product prices more than proportional to the rise in wage rates, since the supply of products produced will fall in greater proportion than the supply of labor employed by business. This is because the labor which is transferred from the employ of business to the

employ of consumers will come at the expense of manufacturing and industries supporting manufacturing, where economies of scale prevail, which now cannot be exploited as fully. This is the case inasmuch as the origin of the rise in the demand for labor is supposed to be precisely a drop in the demand for luxury products of manufacturing.

If the rise in demand for labor is brought about by taxation, the negative effects are far more serious. First of all, in this case, the change in demand represents a virtual deadweight loss to whoever must pay the taxes.¹¹¹ To continue with Ricardo's assumption that it is only capitalists and landlords whose demand for consumers' goods is replaced by a demand for consumers' labor, the situation now is that these parties are compelled to give up the purchase of various luxuries in order to pay for various government expenditures. In place of the "fine clothes and costly furniture" they would have bought for themselves, they now obtain the dubious benefit of the existence of "large fleets and armies," or some peacetime equivalent. Furthermore, because the funds are obtained by taxation, that is, involuntarily, by force, and thus the change in the pattern of demand does not reflect the free choice of the owners of the funds, it cannot be expected that the owners will pay the taxes simply at the expense of their consumption expenditure. Indeed, the major effect of any such tax—any tax whatever that is aimed at the income or consumption of businessmen and capitalists (including, of course, "landlords")—is to reduce saving, the relative demand for and relative production of capital goods, and thus the accumulation of capital, the productivity of labor, and real wages. It is also to reduce the incentive to improve products and methods of production and thus the productivity of capital goods, thereby raising the maintenance proportion, all of which compounds the destructive effects on capital accumulation and the productivity of labor.¹¹² Finally, it is to reduce the wage "share" of national income, further adding to the reduction in real wages. A similar "boomerang" effect exists in connection with efforts to limit the consumption of businessmen and capitalists.¹¹³

Ricardo assumed that the additional tax fell on the consumption of capitalists and landlords rather than wage earners. In reality, the tax would more likely fall on the consumption of wage earners. Only to the extent that it did, would the destructive effects on saving and capital accumulation be mitigated.¹¹⁴ However, even if the tax fell entirely on the consumption of wage earners, it would still do substantial damage.

This is because even if the effect of the government's larger payroll were more employment, the great majority of wage earners, who are already employed and who must pay the tax, must forego part of their own consump-

tion in order to finance the consumption of the additional government employees. Like the capitalists and landlords in the case already considered, they receive little or no compensation for their reduced consumption by virtue of the activities of those government employees. To the contrary, the government's additional employees may very well render their lives more difficult, through imposing additional regulations and controls on them, on the suppliers they buy from, or on the employers they work for or might work for.

If the government's additional demand for labor comes at a time of full employment and so raises the average money wage rate in comparison with what it was before, the standard of living of the wage earners is likewise reduced. For in this case, there is a rise in the prices of consumer goods as great as the rise in wage rates, and, over and above this, a rise in taxes. Thus, the average worker finds that his take-home pay does not keep pace with the rise in prices. The consequences here can be understood in terms of our previous example of the rise in demand for labor from 400 monetary units to 500 monetary units. If the 100-monetary-unit rise in taxes and the demand for labor is paid for by taxes on wage earners, then wage earners as a class are in the position that their after-tax wages are no higher than they used to be, while prices are now 25 percent higher. For in this case, while total wages are 500 monetary units, the taxes paid out of wages are 100 monetary units. Thus, there are still just 400 monetary units in total after-tax wages to be paid to the same total number of workers. At the same time, prices are 25 percent higher, both on the foundation of 25 percent higher wage rates and labor costs and on the foundation that only four-fifths of the previous labor is available to produce consumers' goods, which are thus produced in only four-fifths the quantity and therefore sell at five-fourths the price. Indeed, even the average government worker is worse off now than he was before. On an after-tax basis, he, too, ends up earning no more than he used to earn, while having to pay higher prices. And even if the government workers were previously unemployed, they are worse off in comparison with what they could have had if they had been reemployed privately and thus have added to the total of output, instead of having to share in the restricted output of others. To whatever extent wage earners are taxed to pay for the government's additional payroll spending, these effects are present.

The Limited Scope for Raising Real Wages Through a Rise in the Demand for Labor

What all of the discussion in this section leads to is the conclusion that the only way in which a rise in the demand for labor and in money wage rates can in fact

benefit wage earners is if and to the extent that people decide to consume less and to save and productively expend more for labor. When, for example, consumption out of dividend and interest payments falls and the funds thereby saved are used by business firms to employ labor, there is a rise in the demand for labor and in wage rates, but no rise in the general consumer price level. Thus, there is a rise in real wage rates.

The consumer price level remains the same in this case because both the aggregate demand for and supply of consumers' goods remain the same. The overall demand for consumers' goods remains the same inasmuch as the additional consumption expenditure of the wage earners resulting from their higher wages merely takes the place of an equivalent reduction in the consumption expenditure of businessmen and capitalists, which is the foundation of the rise in wages and the consumption of the wage earners. At the same time, in contrast to the previously considered case of a rise in the demand for consumers' labor, here there is no bidding away of part of the supply of producers' labor in favor of consumers' labor as an accompaniment of the rise in wages, and thus no reduction in the supply of consumers' goods produced. Thus, with both the supply of and the demand for consumers' goods remaining the same, the result is that the general consumer price level remains the same. At the same time, of course, the rise in the demand for labor raises wage rates. Thus, real wage rates rise.¹¹⁵

Precisely this case, which is characterized by a change in demand from consumption to saving and productive expenditure, represents a rise in the so-called distribution factor in favor of wage earners. It is an aspect of a rise in the economic degree of capitalism. And because of this, it is necessary to refine the expression of the distribution factor. It is now clear that stating it simply as the demand for labor relative to the demand for consumers' goods is too broad. It must be stated as the demand for labor *specifically by business enterprises*—that is, the demand for producers' labor—relative to the demand for consumers' goods. This refinement was not necessary so long as the only demand for labor under consideration was the demand for labor by business. Now that the demand for labor by consumers has been introduced, however, and has displayed very different characteristics, the refinement in definition is necessary.

What is present in cases of a rise in the distribution factor is a fall in *net consumption*, which, as I indicated in the last chapter, and will explain more fully in Chapter 16, is consumption in excess of wage payments, made possible by consumption out of such sources of funds as dividend and interest payments.¹¹⁶ A fall in net consumption, I will show, operates to reduce the general or average rate of profit and interest in the economic system,

and this explains why in cases of this kind the rise in costs of production constituted by the rise in wage rates does not operate to raise the general consumer price level—namely, it is offset by a fall in the rate of profit.¹¹⁷

The ability of a fall in net consumption to bring about a rise in real wages by means of raising the demand for labor and thus changing the distribution factor in favor of labor is strictly limited, however. Moreover it is operative only in an environment of security of property, in which people voluntarily choose to consume less and save more. In the present-day United States, net consumption on the part of all private individuals combined almost certainly equals substantially less than 10 percent of national income. This can be inferred by starting with the fact that normally less than 30 percent of national income represents profits and interest, or any other income that is not wages or salaries. Of this 30 percent, half or more can be assumed to be siphoned off in federal, state, and local corporate and personal income taxes. Something on the order of half of the remaining 15 percent of national income in the form of profits and interest can be taken as representing saving out of such incomes.¹¹⁸ Thus, an amount equal most probably to something on the order of 7.5 percent of national income remains as private net consumption.¹¹⁹

It follows that even the total disappearance of today's private net consumption and the use of all of the resulting additional savings to make an additional demand exclusively for labor, would be capable of raising the demand for labor, and thus average wage rates, only on the order of 10 percent. The figure of 10 percent results from dividing the 7.5 percent of national income that can be taken as today's private net consumption, by the approximately 70 percent of national income that is typically in the form of wage or salary payments. Of course, whatever the precise figure for it might be, the rise in the demand for labor and in wage rates would be on a one-time, nonrepeatable basis only.

In fact, however, the disappearance of private net consumption could never take place, because, as we have seen, businessmen and capitalists have no motive to save and accumulate capital except as a means of ultimately contributing to their own consumption. Thus, their consumption cannot be eliminated without destroying the economic system. Nor can it even be significantly reduced by means of force without inflicting major damage on the economic system.¹²⁰ Net consumption is at a minimum precisely in a society in which property rights are fully respected and in which a high degree of rationality leads people to be future oriented and adopt a low time preference. In such conditions, the motive to accumulate for the future rather than to consume in the present is at a maximum. The attempt to use force to bring

about a still further fall in net consumption (or to use force to cause a fall in net consumption under any conditions) results in property becoming insecure and thus in the loss of incentives to accumulate and maintain capital. As we have seen, this destructive process entails a reduction both in the relative production of capital goods and degree of capital intensiveness and in the productivity of capital goods.¹²¹ Depending on the extent of the use of force, the consequences range from the slowing of capital accumulation and rise in real wages to outright capital decumulation and falling real wages. In all cases, the effect is to reduce real wages, at least in comparison with what they would otherwise have been.

Nevertheless, as the result of the existence of improper government activity on a large scale, there is today a significant potential source of a fall in net consumption and rise in the demand for labor by business relative to the demand for consumers' goods. This is *a reduction in government spending and thus in budget deficits and in the taxes that fall on saving and productive expenditure*. If government spending and the funds the government takes to finance that spending were reduced, more funds would be left to business enterprises to expend in meeting payrolls and in buying capital goods. The effect would be a significant one-time rise in the ratio of demand for labor by business to demand for consumers' goods. Of course, far more significant for the long-term rise in real wages would be the accompanying rise in the relative production of capital goods and in the degree of capital intensiveness. These, together with the greater incentives to technological progress and efficiency that would come from reduced government regulatory activity and reduced taxation, would bring about a sharply higher rate of capital accumulation and thus a sharply higher rate of increase in the productivity of labor. Thus, real wages could be increased at first in significant part on the basis of a rise in the demand for labor and then, thanks to the continuing stimulus given to capital accumulation and the productivity of labor, go on increasing without limit.¹²²

The potential for raising real wage rates through a rise in the demand for labor by business relative to the demand for consumers' goods—viz., through a rise in the distribution factor—is always highly limited, even in conditions in which the demand for labor by business relative to the demand for consumers' goods is very modest. In such conditions, increases in the demand for labor by business are accompanied by substantial increases in the supply of labor drawn from the ranks of manual workers who are not wage earners. For example, imagine a society in which the demand for labor is 100

units of money while the demand for consumers' goods is 1,000 units of money. Imagine also that only one manual worker in ten is a wage earner. In these conditions, a doubling of the demand for labor is likely to be accompanied by approximately a doubling of the proportion of manual workers who are wage earners.

As a result, in these conditions, the rise in demand for labor does not raise money wage rates correspondingly. In addition, because the increase in the supply of wage earners does not mean any overall increase in the amount of labor actually performed in the society, it is not accompanied by any corresponding increase in the supply of consumers' goods. Thus, while wage rates stay basically the same, there is also no fall in the prices of consumers' goods caused by an increased supply of labor, and thus real wages cannot rise in proportion to the rise in the demand for labor. In terms of our formula showing real wages as determined by the product of the distribution factor times the productivity of labor, the rise in the distribution factor in these circumstances is accompanied by an apparent decline in the productivity of labor. The decline in the productivity of labor must be termed apparent because it signifies only that as manual workers change their status from non-wage earners to wage earners, the supply of consumers' goods produced increases to a much lesser extent than does the supply of wage earners. The main significance of the distribution factor in this context is that of a gauge of the proportion of the manual workers who are wage earners.

Of course, as such, the rise in the distribution factor indirectly does represent some significant rise in real wage rates. In bringing about a rise in the proportion of manual workers who are employed as wage earners, it is the basis of an increase in the division of labor and thus of a rise in the productivity of labor. As a result, while the supply of consumers' goods produced does not rise in proportion to the number of workers who are wage earners, it does rise relative both to the total number of workers and to the number who are wage earners, and thus prices do decline relative both to money incomes in general and to wage rates in particular. However, what is responsible for the improvement is the rise in the productivity of labor, not the rise in the distribution factor itself.¹²³

Increases in the distribution factor signify directly corresponding increases in real wage rates only insofar as the proportion of manual workers who are wage earners can be assumed to be fixed. This assumption is perfectly reasonable in the conditions of modern, industrial economies, in which almost all manual workers are already employed as wage earners. In this case, increases in the distribution factor signify increases in wage rates in the face of unchanged prices of consumers' goods. But

in this case their potential for raising real wage rates is even more limited, for the reasons explained.¹²⁴

6. Critique of Labor and Social Legislation

It is now possible to turn to a critique of the doctrine that labor and social legislation have been responsible for the rise in the average worker's standard of living.

Redistributionism

It should be obvious that the belief that economic conditions in the past were poor because of an unjust "distribution" of wealth and income, and were improved by the imposition of a more just distribution of wealth and income, is completely wrong. In the early years of capitalism, and in all of history preceding capitalism, there was virtually nothing to redistribute. The workers of the early nineteenth century did not lack automobiles and television sets because the capitalists were keeping the whole supply to themselves. There simply were no automobiles or television sets—for anyone. Nor did the workers of those days lack sufficient housing, clothing, and meat because the capitalists had too much of these goods. Very little of such goods could be produced when they had to be produced almost entirely by hand. If the limited supplies of such goods that the capitalists had could have been redistributed, the improvement in the conditions of the workers would hardly have been noticeable. If one person in a thousand, say, is a wealthy capitalist, and eats twice as much and has twenty times the clothing and furniture as an average person, hardly any noticeable improvement for the average person could come from dividing the capitalist's greater-than-average consumption by 999 and redistributing it. At the very best, a redistribution of wealth or income would have been useless as a means of alleviating the poverty of the past.

Worse than that, it would have been positively harmful for the well-being of the average person. As I have shown, the overwhelming bulk of the wealth of the capitalists is in the form of capital goods, on which the productivity of labor depends. A policy of seizing the wealth of the capitalists, to improve the consumption of the masses, is actually a policy of capital decumulation, which must destroy the foundations of the productivity of labor and thus real wages.¹²⁵

As I have shown, redistributionism through a policy of taxation of the capitalists' incomes and estates reduces the incentive and means for capital accumulation. It reduces saving and productive expenditure and thus the economic degree of capitalism, and with it both the demand for capital goods relative to the demand for consumers' goods and, however ironically, the wage "share" of national income. At the same time, it reduces the incentive to search out and

implement technological advances, and the incentive to be efficient in the use of capital goods. Thus it reduces the productivity of capital goods and raises the maintenance proportion. In other words, it does everything possible to impair the increase in the supply of capital goods and thus the increase in the productivity of labor. It does everything possible to hold down the rise in real wages, and actually to reduce real wages.¹²⁶

The truth is that what made possible the rise in real wages and the average standard of living over the last two hundred years is precisely the fact that for the first time in history the redistributors were beaten back long enough and far enough to make large-scale capital accumulation and innovation possible. What distinguishes eighteenth and nineteenth century Britain and America is precisely the respect shown for property rights. It was this that provided the indispensable foundation for the accumulation of capital and the rise in the productivity of labor and real wages. To the extent that the redistributors have subsequently been able to reimpose their philosophy, the rise in real wages and the average standard of living has been less than it otherwise would have been.¹²⁷

As I have shown, the major victims of redistributionism are always the wage earners. Taxes imposed on profits and interest are paid largely with funds that otherwise would have been used to purchase labor services and capital goods. Taxes imposed on inheritances fall almost entirely on funds that otherwise would have been used in this way. In contrast, there are the taxes imposed directly on wage earners, which cannot be passed on to anyone insofar as they are imposed on workers in all industries and all occupations. To the extent that taxes are imposed on wages in this way, they simply reduce the benefit the average worker derives from the labor he performs. They make the conditions of the average wage earner equivalent to what they would be if the productivity of labor were lower. (The effects of a consumers' sales tax are essentially similar.) However, insofar as taxes are imposed on profits, interest, and inheritances, they not only make the conditions of the workers equivalent to what they would be if the productivity of labor were lower, but have the further effect of retarding or altogether stopping any further rise in the productivity of labor, and thus of making the worsened conditions longer lasting or even permanent. Indeed, such taxes have the potential for plunging the economic system into capital decumulation and economic retrogression, by virtue of bringing about a relative production of capital goods and productivity of capital goods insufficient for the replacement of existing capital goods. Thus, as I have shown, from the point of view of the long-run interests of the wage earners, taxes falling on profits,

interest, and inheritances are actually *worse* than taxes falling directly on wages.¹²⁸

It is necessary to deal briefly with the special fallacies present in the belief, so prominent in the labor-union movement, that profits can be converted into additional wage payments. The labor unions have only to see significant profits, and immediately they believe that a source of additional wage payments exists, which can serve to raise the wage rates of their members.¹²⁹

The fact is that, apart from all the other considerations I have raised against the redistribution doctrine, profits as such are not actually available for redistribution. Profits are not, as most people appear to believe, a separable part of sales revenues that goes to the businessmen and capitalists, and which potentially could go elsewhere. All of the sales revenues go to the businessmen and capitalists, who in turn expend the far greater part of those revenues in the purchase of capital goods and labor. The separable part of sales revenues that goes to the personal use of the businessmen and capitalists is not profits but *dividend* payments, and the draw of funds by partners and proprietors. Profits themselves are actually an accounting abstraction—the difference between sales revenues and historical costs, that is, costs derived from previous outlays for labor and capital goods, made years in the past in many cases. They are *not* the difference between sales revenues and current outlays for labor and capital goods.

Profits can exist with no portion of sales revenues going to the personal disposition of the businessmen and capitalists; they can exist with 100 percent of sales revenues being used to purchase capital goods and to pay wages. For example, a firm could have sales revenues of a million dollars a year and expend the equivalent of the whole of its sales revenues in the purchase of capital goods and the payment of wages, and still have a profit—possibly, a very substantial profit. It would have a profit to the degree that the costs it deducted from its sales revenues were less than a million dollars. Its costs would be less than a million dollars, insofar as the million it spent in each year for capital goods and labor was for the purchase of durable equipment or for the accumulation of inventory.

If, for example, half of its outlay in each year were for equipment that would last ten years, and another quarter of its outlay represented the accumulation of inventory, its total costs deducted from sales revenues in that year on account of expenditures made for capital goods or labor in that year would amount to a mere \$300,000, and thus its profit to as much as \$700,000. This is because of its \$500,000 of outlay for equipment, only \$50,000 would show up as depreciation cost that year. And of its remaining \$500,000 of outlay, only the \$250,000 that does not go for inventory accumulation would show up as a cost

that year. Thus, its total costs on account of expenditures made in that year for capital goods and labor would be no more than \$50,000 plus \$250,000, or \$300,000 in all.

To calculate the firm's overall, total costs in that year, one would, of course, have to add depreciation costs resulting from expenditures for plant and equipment made in prior years. If this amounted to another \$100,000, say, then its profit would still be \$600,000, even though in the same year that its sales revenues were a million dollars, it expended a full, equivalent million in the purchase of factors of production.

In this case, if a labor union demanded the payment of the profit as additional wages, the only possible source of the funds would have to be a reduction in the firm's expenditure for capital goods, or, however absurd, its existing expenditure for labor! Or the funds would have to come from outside the firm, which would entail a reduction in wage payments and the demand for capital goods elsewhere.

Not only in this case, but in every case without exception, the only significant funds which can be added to the payment of wages in any given firm are funds which are withdrawn from the purchase of capital goods in that firm, or from the purchase of capital goods or payment of wages in other firms. As I have shown, funds used to finance the personal consumption expenditure of businessmen and capitalists are not only not significant relative to wages, but also cannot even be obtained as a source of additional wage payments without damage to the economic system on a vastly greater scale. This last is because so long as the businessmen and capitalists retain their capital, they have the power to go on consuming with little or no diminution, while if they lose that power, they lose the incentive to accumulate and maintain capital.¹³⁰ We already know the destructive effects of forcibly increasing the demand for labor at the expense of the demand for capital goods.¹³¹

Furthermore, the notion of converting profits into the payment of wages is held in ignorance of the fact that a substantial portion of profits exists as the result of nothing more than the increase in the quantity of money and volume of spending in the economic system. Such profits reflect the fact that productive expenditure and sales revenue in the current period are greater than the productive expenditure of the past, on which the costs deducted from sales revenues in the current period are based. The growth in productive expenditure from year to year naturally takes the form of rising wage payments and increasing spending for capital goods. At the same time, the rising sales revenues it causes in each year generate profits because, as I say, the costs of each year reflect productive expenditures of the past, which were smaller.¹³² Thus, to the extent that profits reflect merely the

growth in spending, they already provide all the benefit to wage earners that they can possibly provide. This is because they are already expended as wage payments or in the purchase of capital goods. To ask that because they are profits they be paid instead as wages, is to ask for the payment of the same sum twice over to the benefit of wage earners.¹³³

And the same is true of real profits, insofar as they reflect merely the increase in the physical volume of wealth in the possession of business firms. This increase in wealth represents additional capital goods, which are used in further production, and additional consumers' goods sold to wage earners. The full benefit of this additional wealth already goes to wage earners. The profit merely marks the increase in such wealth. It is not available in any way further to increase the benefits to wage earners.

On the basis of our previous discussion both of the cause of higher real wages and of the effects of redistributionism, it should be clear that the attempt of the labor unions to convert profits to wages by means of force cannot raise the average worker's standard of living and must actually tend to reduce it. As I have shown, it is in part an attempt to raise the wages paid to one set of workers at the expense of the wages paid to another set of workers, by virtue of requiring funds to be withdrawn from the payment of wages in some firms in order to be added on to the payment of wages in other firms. And for the rest, it is an attempt to raise wages and consumption at the expense of the demand for capital goods. Insofar as it may succeed in reducing profits, it does so only as the accompaniment of a reduction in the rate of economic progress and thus in the increase in real wages. It slows the increase in production, which reduces both the real profits of business and the rise in real wages.¹³⁴

Labor Unions

This brings me to the general subject of the effect of labor unions on real wages and the wage earners' standard of living.

The productivity theory of wages implies that the labor unions (and the public at large) have an utterly wrong idea of how the average level of real wages and the average standard of living are increased. The goal of the unions is to increase the money incomes of their members. And that, of course, is the goal of practically every individual with respect to his own wages. But I have shown that almost all of the ways of accomplishing a rise in the general or average level of money wages cause either no increase in real wages and the general standard of living or actually *reduce* real wages and the general standard of living—by bringing about unemployment or a lower productivity of labor. I have shown

that the general level of real wages and the average standard of living are simply not raised to any significant sustainable extent by virtue of the average worker earning more money, but only by virtue of the productivity of labor rising and prices falling. I have also shown that the only major way that everyone can earn more money is by virtue of an increase in the quantity of money, which raises prices as much as wages, and that in that case only a rise in the productivity of labor makes it possible for prices to rise less than wages and so enables the rise in wages to represent an increase in real wages.

I now must reconcile the perception of individuals, that the way to raise their standard of living is by earning more money, with the productivity theory of wages, which shows that the general standard of living does not rise by virtue of the earning of more money, but by virtue of the rise in the productivity of labor and the consequent fall in prices relative to wages.

When an individual increases the productivity of his own labor, whether by becoming more efficient in a given job or by raising his level of skills to the point of being able to perform a more demanding job, the likely result is that he will increase his money income. What enables the individual to increase his money income in this way is partly the fact that, at the same time that he is increasing his productivity, the quantity of money and volume of spending in the economic system are also probably increasing. But this is not the major reason for people concluding that greater productivity means correspondingly more money income. A close connection between the individual's improvement in his productive ability and an increase in his money income would exist even if the quantity of money and the volume of spending in the economic system remained constant. It would exist insofar as the improvement in the productivity of the individual's labor is an improvement *relative to the productivity of labor of his competitors in the rest of the economic system*.

In considering the relationship between the improvement in his productivity and the increase in his money income, the individual is usually not aware that what is decisive for his being able to earn a higher money income is the rise in his productive ability *relative to* productive ability in the rest of the economic system. He experiences the improvement in his productive ability as an absolute improvement, not a relative improvement. In his mind, he does better and so he is paid better.

Nevertheless, what actually enables the improvement in his abilities to result in bringing him a higher money income is that it is an improvement relative to the abilities of other people. If everyone improved his productive ability at the same time and to the same extent, no one would earn any more money than before—except to the

extent that there was an increased ability to produce the commodity used as money. There would be an increase in the supply of goods relative to the supply of labor, real wages and the standard of living would rise, but the improvement would be achieved through a fall in prices in the face of unchanged wages, not through a rise in wages.

As an illustration of the fact that the greater productive ability of an individual results in a greater money income for him only insofar as it represents a greater *relative* productive ability, consider the following case. An individual who works in an office or a factory wants to be promoted to manager and thereby earn a higher income. If all that happens is that he improves his performance and now surpasses all of the other candidates for the job, he will most likely be promoted and earn the higher income. But suppose that one or more of the other candidates improve their performance just as much as he improves his. Then his improvement is definitely no guarantee of his being promoted and earning a higher income. The improvement in his performance, the improvement in the performance of all of the competitors, will still tend to raise the general standard of living, through its effect on the supply of goods and services available to the firm's customers, but it will not tend to raise the income of any of the competitors themselves, except insofar as the improvement in the performance of one of them *surpasses* the improvement in the performance of the others or enables their performance as a group to surpass the performance of other such groups.

This last points to the fact that the same principle applies between firms and industries. Insofar as an improvement in the productive ability of some or all individuals within a given firm creates a competitive advantage for that firm, the result might be that some or even all of its employees now earn more money. But in that case, the firms in the industry that lag behind, and their employees, suffer corresponding reductions in revenue and income. If all the firms in an industry are inspired to become more productive, it might be that they all increase their revenues and incomes. But then they do so in competition with other industries, whose firms and employees suffer corresponding reductions in revenue and income. Once again, we are driven to the fact that the only way that everyone in the economic system can earn more money is insofar as there is a larger quantity of money and thus greater volume of spending in the economic system as a whole. More production by itself does not produce this result.

In fact, as I have already shown, there are numerous cases in which, when everyone does increase his ability to produce, the average member of the group actually earns less money. The example of the potato growers, in

the discussion of Say's Law, was precisely such a case.¹³⁵ The same sort of situation exists in cases often cited by labor-union supporters, in which the adoption of piecework stimulates all of the workers to improve their efficiency and results in such an increase in the supply of the product and fall in its price, that the wage per piece falls to the point where most, or even all, of the workers in the occupation earn less than before. In such a case, there is still, of course, an improvement in the general level of real wages and the average standard of living. But before the pieceworkers can participate in it, some of them must leave the field and find other jobs, just like the potato growers. What is present in this case is that piecework so increases the productivity of labor in the particular occupation, that a temporary relative overproduction of the product and oversupply of labor exists in this particular line, accompanied, of course, by a corresponding underproduction of products and under-supply of labor elsewhere. The adoption of labor-saving machinery frequently produces such results.

The efforts of individuals to improve their well-being by earning more money are perfectly reasonable and actually harmonious, even in circumstances in which the existence of a given quantity of money and a given volume of spending for consumers' goods and labor would imply that to the extent that any individual or group succeeds in earning more money, other individuals or groups must earn correspondingly less money. I demonstrated this back in Chapter 9, in showing that the fall in prices would be sufficient to provide higher real incomes to all, provided they made the necessary changes in occupation.¹³⁶

The principle I established there was that everyone gains in real terms, in accordance with the increase in his productivity, but only those gain in monetary terms whose productivity rises by more than the average, that is, rises *relative* to the productivity of the average producer. Naturally, to the extent that a simultaneous increase in the quantity of money and volume of spending goes on, a corresponding general rise in money incomes takes place.

This then is the nature of the connection between the productivity of labor of the individual and the money wages of the individual. It appears to the individual that his gain is in the form of more money, because he considers the effects of an improvement in the productivity of his labor on the assumption of *all other things being equal*—specifically, the productivity of the labor of others being equal and the buying power of money being equal. This is perfectly understandable, in that an individual has very substantial control over the productivity of his own labor, while he has virtually no control over the general productivity of labor in the economic

system as a whole, and virtually no control over the buying power of money. As far as matters are up to him, the general or average productivity of labor in the economic system, and the buying power of money, go on being whatever they are—all that changes is his own individual productivity. On this basis, it appears to him that the way he improves his standard of living is by earning more money, for in such circumstances, a rise in the productivity of his own labor will bring him more money, which will enable him to buy correspondingly more.

Thus, the earning of a higher money income is the reasonable way for an *individual* to attempt to raise his standard of living. And insofar as individuals seek to increase their money incomes through production and exchange, in an environment of freedom of competition, the effect of their actions is to increase their real incomes whether they succeed in earning higher money incomes or not. In such conditions, win, lose, or draw in terms of money, they all win in real terms, because what is fundamental and essential is not that the individual earns more money, but that, in the quest to earn more money, he produces more goods. That is the actual basis on which the standard of living of everyone rises, whether given individuals in a given case end up earning the same, more, or less money.

Unfortunately, most people, and especially the supporters of labor unions, view the earning of more money as the fundamental and essential phenomenon and mistakenly assume that everyone could be made better off simply by the earning of more money. Insofar as individuals act in a private capacity, this mistaken belief results in no direct harm. But when they act in a public and collective capacity and seek to elevate money wages by means of force, through the coercive methods of labor unions or otherwise, then the result is very harmful indeed. This is because, as I have shown, the earning of a higher money income is simply *not* a reasonable way to attempt to raise the *general or average* standard of living.

When the unions seek to raise the standard of living of their members by means of raising their money incomes, their policy inevitably reduces to the attempt to make the labor of their members artificially scarce. The unions do not have much actual power over the demand for labor. But they often achieve considerable power over the supply of labor. And their actual technique for raising wages is to make the supply of labor, at least in the particular industry or occupation that a given union is concerned with, as scarce as possible.

Thus, whenever possible, unions attempt to gain control over entry into the labor market. They seek to impose apprenticeship programs, or to have licensing require-

ments imposed by the government. Such measures are for the purpose of holding down the supply of labor in the field and thereby enabling those fortunate enough to be admitted to it, to earn higher incomes. Even when the unions do not succeed in directly reducing the supply of labor, the imposition of their wage demands still has the effect of reducing the number of jobs offered in the field and thus the supply of labor in the field that is able to find work.

If the unions were confined to just one or a small number of industries, and did not have the power to determine wage rates in the rest of the economic system, their achievement of higher wages in particular industries would not cause unemployment in the economic system as a whole. The workers displaced from the unionized industries would be able to find work—at lower wages—in the nonunion industries. The effect of unions in these circumstances would be the creation of an artificial inequality of wages—higher wages in the unionized fields, based on an artificially imposed scarcity of labor in those fields, accompanied by correspondingly lower wages in the nonunion fields, based on an artificially imposed oversupply of labor in those fields.¹³⁷

A further consequence of this process would be some significant reduction in the average productivity of labor in the economic system. This is implied by the fact that the artificially imposed pattern of employment would be equivalent to the pattern of employment that would result if the workers in the economic system possessed fewer skills, or less potential for developing skills, than they actually do. If those people denied entry into occupations had never had the ability to gain entry in the first place, the result would be equivalent to the unions' keeping them out. The lesser degree of ability implied is the basis for inferring a lower general productivity of labor. The further implication of this is that even if the powers of the unions did not go beyond those of this case, their effect would be not simply to reduce the standard of living of some workers by as much as they raised the standard of living of other workers, but to reduce the standard of living of some workers by *more* than they raised the standard of living of other workers—in other words, to bring about a net reduction in the overall average level of real wages. This is because what is involved in this case is not only that some wage earners earn higher wages while others earn correspondingly lower wages, but also that the supply of goods produced is less—to the extent that a forced reduction in the exercise of skills is present.¹³⁸

The artificial wage increases imposed by the labor unions result in unemployment when the unions have the power to raise wage rates throughout the economic system, or when the wage increases they achieve in particular

fields take place alongside the existence of minimum-wage laws. A rise in wage rates throughout the economic system creates unemployment in virtually every line of work, and leaves no avenue open for workers displaced from any one branch of production to find work in another.

To achieve such a system-wide increase in wage rates, it is not necessary that the entire economic system actually be unionized, or even that the greater part of the economic system actually be unionized. It is sufficient merely that some substantial portion of the economic system be unionized and that the potential exist for the nonunion portions easily to become unionized. If it is possible for unions to be formed easily—if, as in the present-day United States, all that is required is for a majority of workers in an establishment to decide that they wish to be represented by a union—then the wages imposed by the unions will be effective even in the nonunion fields. Employers in the nonunion fields will feel compelled to offer their workers wages comparable to what the union workers are receiving—indeed, possibly even still higher wages—in order to ensure that they do not unionize. The nonunion employers will be likely to believe that if they do not pay wages comparable to union wages, then they will be faced with a union and, as a result, not only union wages, but the loss of major management prerogatives concerning the efficiency of production, and thus experience an even greater increase in costs than is incurred merely by matching union wages.

Furthermore, even if the wage increases caused by the unions are not universal, they will still certainly result in unemployment if they take place alongside the existence of minimum-wage laws and public welfare assistance. Widespread wage increases closing large numbers of workers out of numerous occupations put extreme pressure on the wage rates of whatever areas of the economic system may still remain open. These limited areas could absorb the overflow of workers from other lines at low enough wage rates. But minimum-wage laws prevent wage rates in these remaining lines from going low enough to absorb these workers. So too does the existence of public welfare assistance, inasmuch as people are not willing to work at such low wages if they can obtain a comparable income without working.

In these ways, labor unions cause unemployment—and unnecessarily low wages for those who work in whatever lines remain open to free competition.

From the perspective of most of those lucky enough to keep their jobs, the most serious consequence of the unions is the holding down or outright reduction of the productivity of labor. With few exceptions, the labor unions *openly combat the rise in the productivity of labor*. They do so virtually as a matter of principle. They oppose

the introduction of labor-saving machinery on the grounds that it causes unemployment. They oppose competition among workers. They force employers to tolerate feather-bedding practices, such as the requirement that firemen, whose function was to shovel coal on steam locomotives, be retained on diesel locomotives. They impose make-work schemes, such as requiring that pipe delivered to construction sites with screw thread already on it, have its ends cut off and new screw thread cut on the site. They impose narrow work classifications, and require that specialists be employed at a day's pay to perform work that others could easily do—for example, requiring the employment of a plasterer to repair the incidental damage done to a wall by an electrician, which the electrician himself could easily repair.¹³⁹

To anyone who understands the productivity theory of wages, it should be obvious that the unions' policy of combatting the rise in the productivity of labor renders them in fact a leading enemy of the rise in real wages. However radical this conclusion may seem, however much at odds with the prevailing view of the unions as the leading source of the rise in real wages over the last hundred years or more, the fact is that in combatting the rise in the productivity of labor, the unions actively combat the rise in real wages. The unions and the public do not realize this because they do not even realize that the productivity of labor is the key to real wages. Instead, they believe that the source of a higher standard of living for the workers is higher money wages, which the unions certainly do seek. But, as we have seen, the unions' efforts along these lines are totally misdirected. The truth is that, while claiming to have the purpose of raising the workers' standard of living, the unions are dedicated to the active combatting of the rise in real wages, along with the creation of artificial inequalities in wages and of unemployment.

Consider, for example, the typical union attitude toward an improvement in machinery, such as computer-controlled typesetting equipment. The unions believe that such an improvement should be opposed, on the grounds that it will cause unemployment of typesetters and tend to reduce their wages. They have absolutely no conception that the improvement actually raises real wages—not immediately of the present typesetters perhaps, *but of all the wage earners throughout the economic system who are buyers of books and other printed matter*. The unions simply do not grasp that the rise in real wages comes about through a lower price of the product, and that it is the real wages of the workers who buy the product, not the workers who produce it, that improvements in productivity raise.

The ignorance of the unions and the public concerning the role of productivity is such that they believe that

whenever there is a rise in the productivity of labor in a given industry, the workers in that industry are automatically entitled to a corresponding increase in wages. They simply do not understand that the improvement operates to raise the real wages of the workers who *buy* the product, and that it is perfectly reasonable and appropriate that the money wages of the workers who produce the product fall in many cases as the result of the improvement—because their labor is temporarily placed in a position of relative oversupply as a result of it.

Indeed, the naïve notions of the unions and the public concerning productivity imply that in industries such as computers and pocket calculators, where increases in productivity have occurred on the order of a hundredfold or more, wages should now be a hundred times or more higher than they were a decade or two ago. By the same token, in other occupations, in which there has been little or no increase in productivity, such as waiting on tables, it follows, on this view, that wages should be no higher now than in the past—indeed, in this particular case, no higher now than centuries ago, when the last improvement in the productivity of labor took place (which was probably the invention of the tray).

Of course, an industry-by-industry determination of wages based on productivity is absolutely absurd. So long as the workers of any industry can be employed in other industries—so long, for example, as the workers who today work as waiters can be employed to produce computers or calculators, or to take the jobs of other workers who can be so employed—their wages must be commensurate with the wages of such workers. And the fact is that their wages do stay commensurate, because where the productivity of labor rises, the basic effect is not to raise the money wages of the workers who produce the product, but to reduce the price of the product, which serves to raise the real wages of all workers who buy the product, including those in occupations in which there is no rise in the productivity of labor. And insofar as the rise in the productivity of labor does not succeed in reducing prices, because of an increase in the quantity of money and volume of spending, the effect of the larger quantity of money is to raise the demand for and wages of all types of labor—in the long run, basically in the same proportion, so that once again, wages remain commensurate in all the various occupations open to the same kind of workers. In other words, improvements in the productivity of labor do not raise real wages occupation by occupation, through higher incomes, but, as we have seen, throughout the economic system, by means of lower prices—prices that, as a minimum, are lower in comparison with the level to which increases in the quantity of money and volume of spending would otherwise have raised them.

In sum, far from being responsible for improvements in the standard of living of the average worker, labor unions operate in more or less total ignorance of what actually raises the average worker's standard of living, and are responsible for artificial inequalities in wage rates, for unemployment, and for holding down the average worker's standard of living.

Minimum-Wage Laws

It should already be clear that minimum-wage laws cause unemployment. It should also be clear that the extent to which they do so depends on the extent of union activity in the economic system. The more the unions close off employment opportunities, the greater is the number of workers forced to seek employment elsewhere, and thus the greater is the downward pressure on wage rates elsewhere. Thus, the greater is the number who will be unemployed as the result of a minimum-wage law, which, in effect, closes the gates in the occupations still free from the imposition of union wage-scales against the workers streaming in from the branches of production subject to union wage-scales.

An important implication of these facts is that the problem of low wages, which a minimum-wage law is intended to remedy, would be far less serious in the absence of the ability of labor unions to impose their artificially high pay-scales. If the power of the unions to impose such pay-scales ceased to exist, wages in the portion of the economic system that presently manages to remain free of union pay-scales would be higher, because fewer workers would need to seek employment in these industries, since they would be able to be employed in what are now the industries subject to union pay-scales.

As a consequence of the unemployment they cause, minimum-wage laws deny many people the opportunity of acquiring work experience and the skills they might have acquired by means of working. In the absence of minimum-wage laws, many of the people who would have become employed at lower wages would not have had to earn such wages for the rest of their lives, but could have qualified themselves, through experience and skills acquired by working, for higher paying jobs later on. By aborting such individual processes of development, a minimum-wage law tends to exert a lifelong depressing effect on people. It both stops them from working and prevents them from becoming qualified for anything better than the kind of low-skilled jobs to which a minimum-wage law tends to apply. As I have shown, these results are particularly true today of black teenagers, who are denied not only the possibility of employment by the minimum-wage laws, but also the possibility of gaining the on-the-job experience and improvement in their skills

that employment would have provided. These teenagers are condemned to a life of poverty on the welfare rolls, largely because of minimum-wage legislation.¹⁴⁰

Although the avowed purpose of minimum-wage laws is to help unskilled workers, by providing them with a better income, their actual effect is to achieve the exact opposite. A minimum-wage law prevents less-skilled individuals from successfully competing with more-skilled individuals. It operates precisely against the least-skilled and most-disadvantaged members of society. As I have shown, in a labor market free of government interference, less-skilled individuals can successfully compete with more-skilled individuals by being willing to work for lower wages.¹⁴¹ In raising the wages of less-skilled workers relative to those of more-skilled workers, a minimum-wage law deprives the less-skilled workers of their ability to compete. It reduces their ability to compete with higher-skilled workers in the same occupation and operates to attract higher-skilled workers into the occupation from other occupations. This last observation, of course, applies equally to wage increases caused by unions. Part of the problem of unemployment in any given industry stems from the attraction to that industry of higher-skilled workers from outside the industry, as a result of wages in that industry being elevated relative to wages in other industries. This compounds the unemployment caused by the reduction in job offerings in the industry that a higher wage rate brings about.¹⁴²

Thus, minimum-wage laws cause unemployment, a lifelong depressing effect on the earnings of many of those forced into unemployment, and harm in particular the least-skilled, most-disadvantaged members of society.

Maximum-Hours Legislation

Although it is generally taken for granted that the effect of maximum-hours legislation is to enable the workers to work less while enjoying the same income—with the cost taken out of the employers' profits—the actual effect of such legislation is correspondingly to reduce the real wages of the workers. This conclusion can easily be shown in terms of our familiar equations for average money wage rates and the general level of consumers' goods prices. Thus, taking the context of the present day, I assume the passage of a law reducing the work week from its present forty hours to thirty hours. I also assume that the respective demands for labor and consumers' goods remain the same, because of the existence of a fixed quantity of money. On these assumptions—using an asterisk to denote the fixity of the demand for labor, and stating the supply of labor in terms of hours worked—our equation for average money wage rates shows:

$$\frac{DL^*}{\frac{3}{4}S_L \text{ (in terms of hours)}} = \frac{4}{3} \text{ Average Hourly Money Wage Rate.}$$

That is, average hourly wage rates increase in the ratio of four to three, as the result of dividing the fixed demand for labor by three-fourths the supply of labor in terms of hours.

At first thought, this may appear to fulfill one of the most ambitious hopes of the union leaders who seek to shorten the work week and who, in order to avoid any reduction in weekly earnings, demand a rise in hourly earnings sufficient to compensate for the shorter hours. In the formulas, the assumption of a constant demand for labor implies that hourly earnings would indeed rise in inverse proportion to the fall in the hours worked and thus that weekly earnings would remain unchanged. But before concluding that this situation would fulfill the hopes of the union leaders, let us consider the effect on the prices of consumers' goods, namely:

$$\frac{DC^*}{\frac{3}{4}S_C} = \frac{4}{3}P.$$

This equation shows that three-fourths the labor performed shows up in three-fourths the supply of consumers' goods produced and sold, and thus, in the face of an unchanged demand for consumers' goods (indicated by the use of an asterisk), in a rise in their price in the ratio of four to three. Thus, prices rise in the same proportion as hourly wage rates. And because weekly wage rates are unchanged (again indicated by the use of an asterisk), inasmuch as

$$\frac{4}{3} \text{ Average Hourly Money Wage Rate} \times \frac{3}{4} \text{ Hours Worked} = \text{Unchanged Average Weekly Money Wage Rate,}$$

the net result is

$$\frac{\text{Average Weekly Money Wage Rate}^*}{\frac{4}{3}P} = \frac{3}{4} \text{ Average Weekly Real Wage Rate,}$$

which means that the rise in consumers' goods prices in the ratio of four to three implies a fall in average weekly real wages in the ratio of three to four. Thus, there is a reduction in real weekly earnings in exactly the same ratio as the hours worked! Not surprisingly, to the degree

that he produces less, the average worker receives less. When he does three-fourths the work, he receives three-fourths the real wages, even if his money wages remain unchanged, for then the supply of goods is three-fourths as great and prices are four-thirds as great.

The principle here is that if less work is done, fewer goods will be produced and goods will be rendered correspondingly scarcer relative to the number of workers, and thus their prices will rise relative to the incomes of the workers—i.e., real wages will decline. This principle applies to every reduction in the hours of work, whether from forty to thirty, as might be contemplated in our day, or from sixty to fifty, or even from eighty to seventy, as occurred in previous generations. Always, less work per worker means less output relative to the supply of labor and thus higher prices relative to wages, and, therefore, a corresponding decline in real wages.

There is certainly no harm in such a drop in real wages, provided the workers can afford it, and value the additional leisure more highly than the real wages they must forgo in order to achieve that leisure. As I have shown, that situation will exist if the productivity of labor has risen sufficiently, in which case the labor market itself operates to bring about a shortening of hours. But there can be great harm from *forced* reductions in the hours of work imposed by maximum-hours laws. These laws force workers to accept lower real wages than they judge they need to have. Their effect is to force poor people to become still poorer, in the misguided belief that their poverty can be alleviated at someone else's expense. Maximum-hours laws did not help to raise the standard of living. Insofar as they took effect concurrently with the rise in the productivity of labor and the consequent reduction in hours achieved by the operations of the labor market, they were superfluous. Insofar as they took effect in advance of the necessary rise in the productivity of labor and the operations of the labor market, they were destructive.

My analysis of the effects of maximum-hours laws, and of labor-union wage demands to offset them, has assumed that the demands for labor and consumers' goods remain constant in the face of higher wages and prices. These assumptions would not be able to hold up in a context of free international trade in which the various countries used the same money. In such a context, there would be movements in the supply of money from country to country, in response to changes in relative wages and relative prices among the various countries. A rise in wages and prices in any one country relative to wages and prices in other countries would be accompanied by a fall in the quantity of money and volume of spending in that country, and a rise in the

quantity of money and volume of spending in other countries, as buyers sought to take advantage of the less expensive markets. The effect would be to cause large-scale unemployment in that country.

To avoid such unemployment, it is likely that a forced shortening of hours would not be accompanied by anything like an inversely proportionate rise in hourly wage rates in the country in which the shortening occurred. More likely, hourly wage rates would show very little increase in that country. Indeed, *they would tend to increase across the world* in inverse proportion to the fall in the *world supply* of labor constituted by the lower hours in this particular country. If, for example, hours are reduced in the ratio of three to four in a country that represents 10 percent of the world economy, this would represent a reduction in the world supply of labor and consumers' goods, not of 25 percent but of only 2½ percent. In this case, hourly wages, and prices, would rise not in the ratio of four to three, but on the order of 100 to 97½, on a world basis. Thus, in the country in which it occurred, the reduction in hours would be accompanied by an almost equivalent decline in weekly money earnings, with prices nearly stable. However, the essential result—the decline in real wages—would, of course, still be the same as before.

The same essential analysis applies insofar as a country has obligated itself to maintain a fixed exchange rate between its currency and the currency of other countries. In this case, if wages and prices in the country were to rise significantly relative to those in other countries, the country's currency would be turned in, in exchange for foreign currencies, which people would now want in greater quantity, in order to be able to buy relatively more cheaply. To be able to meet the demand for foreign currencies at the fixed exchange rate, the country's government would have to contract the supply of its own currency, in order to reduce such demand. Thus the result would be much the same as under a single international money.

Child-Labor Legislation

The abolition of child labor is certainly something that is highly desirable, just as is the shortening of the hours of work. But, like the shortening of hours, it is desirable only when it can be afforded. In order for this to happen, it is necessary first that the productivity of labor rise to the point where parents no longer need the labor of their children to help make ends meet. As I have shown, as that point is approached, child labor gradually disappears, simply by virtue of the decisions of more and more parents to keep their children home longer and longer.

The abolition or reduction of child labor by law, rather than by the voluntary decisions of parents in a progress-

ing economy, ignores the precondition of the productivity of labor being high enough to enable the parents to afford its reduction or abolition. As a result, child-labor laws have had the perverse effect of rendering poor families still poorer, and, in so doing, of jeopardizing the health and well-being of the very children they were intended to protect.

In essence, their effect can be understood by imagining the conditions of an isolated family on a desert island, such as Swiss Family Robinson. The family needs the labor of its children if it is to survive or achieve some minimal degree of well-being. Now a social worker comes to the island to observe the family and he decides that he does not like the fact that the children are working. He later returns with a policeman and forcibly prevents the children from working. The actions of this social worker could certainly not be said to promote the lives and well-being of the family members in general or of the children in particular. He would simply force that family to be poorer and more wretched than it needed to be, including its children. This is the effect of a child-labor law on a desert island. Its effect in society is no different. This is because in society too, the real income of a family depends on the amount of work its members perform. And when they perform work that may appear excessive by the standards of those who are more affluent, it is usually because they have a real need to do so.

Child-labor laws do not deserve credit for the abolition of child labor. The abolition of child labor was an accomplishment of capitalism and the rise in the productivity of labor it achieved. As in the case of maximum-hours laws, insofar as child-labor laws merely ratified the abolition of child labor already being achieved by the market, they were superfluous. Insofar as they went ahead of the market, and imposed reductions in child labor beyond what parents judged their families could afford, they were destructive. Along with depriving poor families of urgently needed income, they had the effect of forcing children to work at lower wages and in poorer conditions than they needed to. This was the result of closing off major categories of relatively desirable employment opportunities, such as were provided by larger employers, and leaving open only lower-paying, less desirable employment opportunities.¹⁴³

A question can arise concerning a possible role for child-labor laws in curbing the actions of parents who do not in fact require the labor of their children, but who would send their children to work out of indifference to their well-being. There certainly are such parents, and a strong case can be made for compelling them to provide better for their children—on the grounds of the right of a child to be supported by his parents to the extent that

his parents have the means of supporting him.

Nevertheless, in an otherwise free society, child-labor laws are not the appropriate means for dealing with this problem, because their scope cannot be limited to such cases. They necessarily have the effect of forcibly interfering with families who are not indifferent to the well-being of their children, but who send their children to work out of economic necessity. To the extent that there is immigration from poor countries, to the extent that there are any significant numbers of poor people who have not yet been sufficiently assimilated into the economic system, there will be poor families who depend on some contribution from their children that would be inappropriate in the context of families that are better off. The destructive consequences of child-labor laws in such cases far outweigh the possible good they might accomplish in prohibiting this one manifestation of parental indifference. As a general principle, it is necessary to realize that even where the particular goal the government seeks to accomplish may be legitimate, its intervention can easily introduce worse evils than it seeks to remedy. This is particularly true as concerns the relations between parents and children.

Forced Improvements in Working Conditions

The same perversity of result—that of harming the very people whom one intends to help—occurs no less in the case of government-sponsored improvements in working conditions. This, of course, includes improvements in working conditions imposed by labor unions in a position to resort to force without fear of prosecution, or which enjoy such legal privileges as the government compelling employers to deal with them.

Insofar as improvements in working conditions do not pay for themselves, their coming into being is equivalent, from the point of view of employers, to a rise in wage rates. It is an increase in the cost of employing workers. (Where the improvements pay for themselves, then, as previously explained, their implementation comes about in the same way as any other improvement in efficiency, such as the adoption of better machinery.)

A forced increase in wage rates, or, as in this case, the equivalent of a forced increase in wage rates, causes unemployment, higher production costs, reduced production, and higher prices. It thus leaves the average worker in the economic system in the position of having to accept a reduction in his real take-home pay, even if he is among those fortunate enough to escape the unemployment. This is because even if he keeps his job, he is confronted with higher prices caused by the additional costs imposed by the forced improvements, while his take-home wages remain the same. Indeed, as we have seen, to the extent that unemployment is caused, the

average worker's take-home pay is actually reduced, by his having to use some portion of his wages to support the unemployed.

If unemployment is not to result, then it is necessary that wage rates fall by enough to compensate for the cost of the forced improvements in working conditions, so that employers do not experience a rise in the cost of employing workers. In either case, the cost of the improvements is at the expense of the real income of the average worker. In the case in which unemployment is created, he earns a reduced take-home money wage (after allowing for his support of the unemployed), and, at the same time, must buy at higher prices, to cover the cost of the forced improvements. In the other case, in which unemployment is avoided, he earns take-home wages that are reduced by enough to offset the cost of the forced improvements, and must buy at the same prices. In either case, the so-called improvements are at the expense of the workers, who cannot afford them.

When this fact is recognized, it becomes clear that "improvements" which must be forced upon the market have no right to be called improvements at all. They appear to be improvements only so long as one does not see that they have to be paid for by the very class of people whose poverty is the source of constant complaint, and whose members are unwilling to bear such costs. In reality, they represent no more of an improvement than forcing a poor person to eat steak instead of hamburger would represent an improvement, given the fact that he must pay for it and thus have less left over for other things, which he regards as more important to have than the out-of-context improvement in his food.

The fact that it is workers who end up bearing the cost of forced improvements in working conditions does not always mean that it is the particular workers whose conditions are improved who bear the cost in the form of lower real take-home wages. It can happen that the higher costs of employing workers in a particular occupation or industry are met by a withdrawal of funds from the payment of wages or the purchase of capital goods elsewhere in the economic system. In such a case, it is the wages of other workers that will tend to fall. In the short run, the wages of the workers who have the benefit of the improvements will be lower only in the sense that the cost of the improvement in their working conditions could just as well have been given to them in the form of higher take-home wages. Their take-home wages are lower in comparison with what they might otherwise have been. In the long run, however, if the freedom of competition exists, there will be a tendency for the take-home wages of these workers to fall, as workers from other lines, where wages have been reduced, move in to compete with them. In addition, to the extent that a

reduction in the demand for capital goods is involved, the supply of goods produced in the economic system will be less, and prices higher, and will be so progressively insofar as a permanent fall in the relative demand for and production of capital goods is present. The essential point here is that wage earners as a group must suffer as the result of forced improvements in working conditions.

7. The Employment of Women and Minorities

The productivity theory of wages provides the analytical framework necessary for understanding the economic effects of the employment of women and minorities under the freedom of competition.

A large segment of public opinion fears such employment on the grounds that it causes unemployment of white-male workers and reduces the wages of white-male workers.¹⁴⁴ It should already be understood that to the extent that the competition of women and minority-group members succeeds in reducing the wages of white-male workers, it does not result in unemployment. On the contrary, it enables any given aggregate demand for labor to employ a larger total number of workers, and thus enables the women and minority-group members to work alongside the white-male workers. In a free labor market, absolutely no unemployment need result from the employment of women or minority-group members.

The productivity theory of wages also shows that the fall in the money wages of the white-male workers that follows from free competition does not mean a fall in their *real* wages. The larger supply of goods resulting from the employment of the women and minority-group members means lower prices. (The lower wages that result also mean lower costs of production.) If the productivity of labor remains the same, the increase in output is precisely in proportion to the increase in the supply of labor employed. And thus, given constant aggregate demands for labor and goods, the fall in prices is fully in proportion to the fall in wages.

If this were all that happened, every married couple would certainly have a considerable gain as the result of the wife going to work. The fall in wages of the husband would be compensated for by the wages earned by the wife, and at the same time prices would fall, so that the actual buying power of the couple would rise. To illustrate this point, imagine that all workers are married and that initially no married women work. Now imagine that all married women work. Thus, the number of workers employed is doubled, and the average money wage per worker is halved. But production too is doubled and prices fall in half. The position of the average couple would be that it earned the same money income and bought at half the prices. Its real income would be doubled.

The actual fact is, however, that the free competition of women and minority-group members, just like the free competition of immigrants, must ultimately operate to *raise* the average productivity of labor, because it means the presence in the productive system of a larger absolute amount of talent. If there are women and minority-group members with the potential to be better foremen or company vice presidents, and so on, than some of the white males holding these jobs, then the effect of their obtaining them under free competition must be to raise the productivity of the workers under them. If the absolute number of productive geniuses is increased in proportion to the employment of women and minority-group members, or even if it is increased only half or a quarter as much, there must be a substantial rise in the average productivity of labor. This is the operation of the pyramid of ability principle.¹⁴⁵

Thus, under the freedom of competition, the employment of women and minority-group members is actually to be welcomed from the point of view of the material self-interests of white male workers.

It must be stressed, however, that this conclusion applies only under the freedom of competition. It does not apply insofar as minimum-wage and pronoun legislation result in a freezing of the overall number of jobs available. Nor does it apply insofar as a system of sexual, racial, or ethnic quotas favors the advancement of less-able women and minority-group members over more-able white male workers. In such conditions, all of the negative results of violations of the freedom of competition are to be found, namely, unemployment, a reduced productivity of labor, and group conflict.

8. The Productivity Theory of Wages and the Wages-Fund Doctrine

The productivity theory of wages incorporates essential features of the classical economists' doctrine of the "wages-fund." As result, it is necessary to explain the wages-fund doctrine and to answer the unjustified criticisms that served to bring it down in the last century and which could otherwise now be directed against the productivity theory as well.

The wages-fund is simply what we have been calling the aggregate demand for labor, i.e., total payrolls. The classical economists recognized it, together with the supply of labor, as determining the level of average wage rates. They also recognized that the demand for consumers' goods is separate and distinct from the demand for labor, and that the prices of consumers' goods are determined by the demand for consumers' goods together with the supply of consumers' goods.¹⁴⁶ Indeed, Cairnes, the last major classical economist, was able to go so far as to

recognize explicitly that "real wages will advance with the productiveness of industry in producing such real wages—in producing, that is to say, the commodities of the laborer's consumption."¹⁴⁷ Nevertheless, the classical economists never succeeded in developing the wages-fund doctrine into the productivity theory of wages. They did not so much as get to the point of carrying out the analysis I presented in Section 2 of this Chapter-part, let alone systematically apply to the determination of the productivity of labor and real wage rates the further critical elements of the theory that I presented in Sections 3 – 6.¹⁴⁸

The explanation is that they were generally pessimistic concerning the prospects for wage earners, mainly because of their failure to realize that a division-of-labor, capitalist society is able to overcome the operation of the law of diminishing returns.¹⁴⁹ As a result, they did not see much potential for a rise in the productivity of labor, and thus did not give much consideration to its ability to raise real wages. Cairnes himself wrote, as late as 1874, "Nothing is more certain than that taking the whole field of labor, real wages in Great Britain will never rise to the standard of remuneration now prevailing in new countries—a standard which after all would form but a sorry consummation as the final goal of improvement for the masses of mankind."¹⁵⁰

Because, as I say, the productivity theory of wages incorporates essential features of the wages-fund doctrine, it is necessary to deal with the objection that is certain to be raised against it, which is that the wages-fund doctrine was refuted in the nineteenth century. Both the substance of the arguments raised against the wages-fund doctrine and the basis for the conviction that it was refuted can be found in the quotation from John Stuart Mill that appears below. For most of his life, Mill had been a leading supporter of the doctrine, but in these famous passages he recants his previous support. Mill's recantation, given his eminent status as the intellectual leader of classical economics in his day, was immediately seized upon as constituting an irrefutable and irrevocable overthrow of the doctrine. Mill writes:

It will be said . . . supply and demand do entirely govern the price obtained for labour. The demand for labour consists of the whole circulating capital of the country, including what is paid in wages for unproductive labour. The supply is the whole labouring population. If the supply is in excess of what the capital can at present employ, wages must fall. If the labourers are all employed, and there is a surplus of capital still unused, wages will rise. This series of deductions is generally received as incontrovertible. They are found, I presume, in every systematic treatise on political economy, my own certainly included. I must plead guilty to having, along with the world in general, accepted the theory without the qualifications and limitations necessary to make it admissible.

The theory rests on what may be called the doctrine of the wages fund. There is supposed to be, at any given instant, a sum of wealth, which is unconditionally devoted to the payment of wages of labour. This sum is not regarded as unalterable, for it is augmented by saving, and increases with the progress of wealth; but it is reasoned upon as at any given moment a predetermined amount. More than that amount it is assumed that the wages-receiving class cannot possibly divide among them; that amount, and no less, they cannot but obtain. So that, the sum to be divided being fixed, the wages of each depend solely on the divisor, the number of participants. . . .

But is there such a thing as a wages-fund, in the sense here implied? Exists there any fixed amount which and neither more nor less than which, is destined to be expended in wages?

Of course there is an impassable limit to the amount which can be so expended; it cannot exceed the aggregate means of the employing classes. It cannot come up to those means; for the employers have also to maintain themselves and their families. But, short of this limit, it is not, in any sense of the word, a fixed amount.

In the common theory, the order of ideas is this: The capitalist's pecuniary means consist of two parts—his capital, and his profits or income. His capital is what he starts with at the beginning of the year, or when he commences some round of business operations; his income he does not receive until the end of the year, or until the round of operations is completed. His capital, except such part as is fixed in buildings and machinery, or laid out in materials, is what he has got to pay wages with. He cannot pay them out of his income, for he has not yet received it. When he does receive it, he may lay by a portion to add to his capital, and as such it will become part of next year's wages-fund, but has nothing to do with this year's.

This distinction, however, between the relation of the capitalist to his capital, and his relation to his income is wholly imaginary. He starts at the commencement with the whole of his accumulated means, all of which is potentially capital: and out of this he advances his personal and family expenses, exactly as he advances the wages of his labourers. . . . If we choose to call the whole of what he possesses applicable to the payment of wages, the wages-fund, that fund is co-extensive with the whole proceeds of his business, after keeping up his machinery, buildings and materials, and feeding his family; and it is expended jointly upon himself and his labourers. The less he expends on the one, the more may be expended on the other, and *vice versa*. The price of labour, instead of being determined by the division of the proceeds between the employer and the labourers, determines it. If he gets his labour cheaper, he can afford to spend more upon himself. If he has to pay more for labour, the additional payment comes out of his own income; perhaps from the part which he would have saved and added to capital, thus anticipating his voluntary economy by a compulsory one; perhaps from what he would have expended on his private wants or pleasures. There is no law of nature making it inherently impossible

for wages to rise to the point of absorbing not only the funds which he had intended to devote to carrying on his business, but the whole of what he allows for his private expenses, beyond the necessaries of life. The real limit to the rise is the practical consideration, how much would ruin him or drive him to abandon the business: not the inexorable limits of the wages-fund.

In short, there is abstractedly available for the payment of wages, before an absolute limit is reached, not only the employer's capital, but the whole of what can possibly be retrenched from his personal expenditure: and the law of wages, on the side of demand, amounts only to the obvious proposition, that the employers cannot pay away in wages what they have not got. On the side of supply, the law as laid down by economists remains intact. The more numerous the competitors for employment, the lower, *ceteris paribus*, will wages. . . .

But though the population principle and its consequences are in no way touched by anything that Mr. Thornton has advanced, in another of its bearings the labour question, considered as one of mere economics, assumes a materially changed aspect. The doctrine hitherto taught by all or most economists (including myself), which denied it to be possible that trade combinations can raise wages, or which limited their operations in that respect to the somewhat earlier attainment of a rise which the competition of the market would have produced without them,—this doctrine is deprived of its scientific foundation, and must be thrown aside. The right and wrong of the proceedings of Trade Unions becomes a common question of prudence and social duty, not one which is peremptorily decided by unbending necessities of political economy.¹⁵¹

It should be obvious that the whole basis of Mill's recantation is demolished by our analysis in Section 5 of the present part of this chapter. There we examined the ability of the demand for labor to increase at the expense of net consumption (*viz.*, the personal consumption expenditure of the businessmen and capitalists) or at the expense of the demand for capital goods. We saw that the ability of the demand for labor to increase at the expense of net consumption is extremely limited and, moreover, cannot be forced. We also saw that an increase in the demand for labor coming at the expense of the demand for capital goods is against the long-run self-interests of the wage earners.

Thus, the fact remains that the only possible basis of a sustained, significant rise in average real wages is a rise in the productivity of labor and that this depends on the economic degree of capitalism and the productivity of capital goods (which depends on technological progress), both of which, in turn, depend on economic freedom—*i.e.*, capitalism in the political sense—and the cultural influence of rationality. We have seen, and will see further, that all the essential tenets of classical economics in general and the wages-fund doctrine in particular concerning the role of saving in determining

both capital accumulation and the demand for labor are absolutely correct. The fact remains, despite Mill's socialistic inclinations, that capitalism, not government intervention and socialism, is the only possible basis of a high and rising standard of living for the average worker.

9. The Productivity Theory of Wages Versus the Marginal-Productivity Theory of Wages

The productivity theory of wages should not be confused with the similarly named *marginal-productivity theory of wages*. The marginal-productivity theory begins with the premise that the value of factors of production (whether labor, land, materials, machinery, or capital in the abstract) is derived in every case from the value of the product produced—for example, that the value of flour is derived from the value of bread, and the value of wheat from that of flour. It rests on the further assumption that it is possible to determine a *physical product* that is uniquely attributable to a factor of production in every given case. It then takes the monetary value of that physical product and calls it the *marginal-value product* of the factor of production.

The reason for the use of the word “marginal” is that the theory is concerned with the determination of the physical and value products of *incremental quantities* of factors of production. For example, it seeks to determine the number of bushels of wheat that are attributable to the employment, say, of a *tenth* farm worker, all other conditions remaining the same. It arrives at such a determination by taking the difference between what is produced, all other things being equal, with the presence of that worker, and what is produced without him (assuming that it is actually possible to do this). If, for example, 10 workers on a given farm, with given equipment, produce 1,000 bushels of wheat per year, while 9 workers on the same farm, with the same equipment, produce only 925 bushels of wheat per year, it is said that the tenth farm worker is responsible for the production of 75 bushels of wheat. Seventy-five bushels of wheat are held to be the marginal-physical product of labor on this wheat farm, given the employment of ten workers on the farm. The *marginal-value* product of labor is then held to be determined by multiplying the marginal-physical product by the price of wheat. If that price is, say, \$1 per bushel, then, it is held, the marginal-value product of a worker is \$75.

The wages of every given type of labor, and the price of every material, semi-finished good, piece of equipment, land site, and so forth, is held to be determined by the combination of a schedule of diminishing marginal-value products, which allegedly represents the demand for the factor of production, and the supply of the factor

of production in question. The wage of every worker and the price of every nonhuman factor of production, it is held, tends to equal the marginal-value product corresponding to the quantity of the factor of production that is used in production. Thus, if the supply of farm labor is such that production on a farm will be carried to the point of using ten workers, the wages of those workers will be \$75 each. If the supply of such labor were less, the wages of those workers would be greater; if it were greater, the wages of those workers would be less.¹⁵²

The productivity theory of wages, in contrast, takes a different view. It is fully compatible with the recognition given by Austrian economics to the fact that the importance of means derives from the importance of the ends which they serve, and thus that ultimately the value of factors of production must derive from the value of the products they produce. However, it does not hold that in each and every individual case this is so. The productivity theory of wages recognizes that in many, indeed, probably the great majority of individual cases, it is simply not possible to establish a marginal-physical product that could be relevant to the determination of the actual value of factors of production.

Even in such a rather simple and contrived case as that of wheat farmers, a serious problem can arise. For example, what if while the output of 10 workers on the farm is 1,000 bushels, that of 9 workers is only 875 bushels? In this case, the marginal-physical product of the tenth worker would be 125 bushels of wheat. If each of the 10 farm workers is to be paid in accordance with the principle of marginal productivity, the total wages paid would exceed the value of the product produced. They would be 10 times 125, or 1250, times the price of the product. Nothing whatever would be left for profit or even to allow for the value of other factors of production.

This kind of problem can be sidestepped so long as the discussion is confined to cases like wheat farming. This is because in such cases the answer can be made that a factor of production will be used in a zone of diminishing returns. Farm workers will be employed to the point where the marginal-physical product of the last one will be low enough so that the payment of wages is not so great as to leave nothing over for the value of the other factors of production and for profit. This is the answer given by Rothbard, for example.¹⁵³ However, even in such cases as farm workers, this answer is dubious, if the assumption is to be maintained that all other things are truly equal. For then, it is quite possible that one less worker means that some important piece of equipment must lie idle, thereby causing a sharp drop in production.

The problems become even more obvious if we apply the methodology of the marginal-productivity theory to materials and components, which must be done insofar

as the value of labor is allegedly derived through the intermediary value of materials or components. Thus, the marginal-productivity theory implies that the price of automobile parts, for example, is determined on the basis of the portion of an automobile's utility that is lost if the part in question is not present. In a case of this kind it is glaringly obvious that the sum of the value of the parts would end up far exceeding the value of the product, if the marginal-productivity theory were correct. This is because if one asks how much of a car's utility or value depends on its having a steering wheel, any one of its four wheels, or accelerator pedal, fuel pump, carburetor, and so on, the answer, over and over again, is the whole value, or at least the far greater part of the value, of the automobile. In the same way, the utility of a television set, or virtually any product, vitally depends on the presence and functioning of a number of parts. In all such cases, if the value of the parts is to be determined by the loss of utility of the product that follows from the absence of the part, the sum of the values of the parts must far exceed the value of the product.

As I showed in Chapter 10, the truth is that in such cases the value of the parts is *not* derived from the value of the product. On the contrary, the value of the parts, and, as a rule, the value of the product itself, is determined on the basis of cost of production. For example, even though the whole utility of an automobile depends on the functioning of its carburetor, one virtually never has to pay a price for a carburetor corresponding to its contribution to the utility of an automobile. One pays the far lower price corresponding to the cost of producing the carburetor. And the price of the automobile itself is, as a rule, actually determined on the basis of the prices of the components, machinery, and so forth together with the wages that must be paid in order to produce it—i.e., on the basis of its cost of production. The truth is that in the great majority of cases, including all the cases of materials, components, and parts, the buyer does not pay a price that comes up to the utility of the particular product in question, but a far lower price, determined on the basis of the product's cost of production. Although it may seem paradoxical, this fact represents the actual operation of the principle of marginal utility, which itself implies that in the first instance the prices of most products are determined on the basis of their cost of production.¹⁵⁴

The productivity theory of wages, as opposed to the marginal-productivity theory of wages, regards wages and the productivity of labor as the fundamental determinants of costs of production, including the prices of materials, components, and machinery, and, by way of determining costs of production, as the determinants of the prices of consumers' goods in most cases. It regards

wage rates themselves, however, (and the prices of land and of raw materials whose supply cannot be quickly adapted to changes in demand) as reflecting the valuations of the consumers of the final products.

But even in stating this last proposition, one must be careful not to concede too much to the role of consumer demand. As I will conclusively demonstrate in the next chapter, the demand for most labor in the economic system is constituted by productive expenditure—that is, expenditure by business enterprises for the purpose of producing products for sale. It comes out of capital, which has had to be saved, not out of consumption expenditure. Given the quantity of money, and thus the total, overall ability to spend, the demand for labor employed by business enterprises varies *inversely* with consumption expenditure, not directly. The influence of the consumers on wages is basically that of determining the relative wages of different groups of workers—above all, the wages of skilled workers relative to those of unskilled workers, and the wages of professional-level workers relative to those of these two groups. And the same applies to the influence of consumer demand on the prices of land and raw materials. The actual causal sequence is that consumer demand determines the prices of the fundamental factors of production relative to one another and these prices in turn then help to determine the prices of most products, including most consumers' goods, relative to one another. (Those products whose value is not determined in this way are determined in value on the basis of their own, direct marginal utility.)¹⁵⁵ The value of means of production is most certainly not derived from the value of the products on a case-by-case basis.

Aside from its naïveté in assuming such derivation, the marginal-productivity theory of wages suffers from the further serious defect of placing the emphasis on the income a worker earns, to the neglect of the prices he must pay for the goods he buys. A sound theory of wages must, as I have shown, concentrate not merely on what determines the money wages of the average worker, but on what determines the *relationship* between those wages and the price of goods. This the so-called marginal-productivity theory of wages totally neglects, in addition to failing in the attempt to explain money wage rates.

The Productivity Theory of Wages and the Effect of Diminishing Returns

The marginal-productivity theory of wages is valuable in one respect, namely, that it calls attention to the law of diminishing returns and to the fact that its operation has an important bearing on real wage rates. Here I will incorporate the operation of the law of diminishing returns into the productivity theory of wages. I have

largely neglected to do this up to now, because, apart from explaining why capital accumulation would come to an end in the face of the operation of the law of diminishing returns not offset by technological progress, I have gone on the assumption of continuous technological progress—technological progress caused in part by the increase in the supply of labor itself.¹⁵⁶

In the absence of technological progress and the capital accumulation it makes possible, a doubling of the supply of labor results in less than a doubling of the supply of consumers' goods—for the sake of illustration, let us say 1.9 times the supply of consumers' goods. Thus the second half of the now larger supply of labor adds an output of consumers' goods of only .9 times the original output. Because both halves of the now larger supply of labor are interchangeable, each of the two halves of the now larger supply of labor will end up with real wages of .9 times the original real wages. Thus, the original workers will experience a 10 percent decline in their real wages. This 10 percent decline in the original amount of real wages represents an equivalent increase in "rents" in the economic system. This is because the inability of production to double is the result of the greater scarcity of land and natural resources, the real income derived from which, and the real value of which, accordingly increases. (Strictly speaking, along with the 10 percent decline in the real wages of the original workers, businessmen and capitalists will experience a 10 percent decline in their real profits and interest derived from investments other than in land or natural resources.)

In terms of money, if the demand for consumers' goods were originally 500 units of money, then in the absence of an increase in the quantity of money, it would tend to remain at 500 units of money. Thus, prices would fall in the inverse ratio of the increase in the supply of consumers' goods, namely, to $\frac{10}{19}$ their original height. If the demand for labor were originally 400 units of money and remained at 400 units of money, the wage earners would be worse off because the doubling of the supply of labor would imply a halving of wage rates, while prices fell by less than half, to $\frac{10}{19}$. However,

under these assumptions they would be worse off only on the order of 5 percent, namely half the money wage rate divided by $\frac{10}{19}$ the price level, which equals a real wage of $\frac{19}{20}$, i.e., a real wage that is $\frac{1}{20}$ or 5 percent less. What the marginal productivity theory helps to stress is that real wages in such a case would not fall merely by 5 percent but by 10 percent, that is, in proportion to the fall in the marginal productivity of labor, which is as .9 to 1. What makes real wages fall this much in the analysis of the productivity theory of wages is that a fall takes place in the *demand for labor* on the order of 5 percent. Thus the average *money* wage rate falls by more than half, which, when combined with the fall in prices of less than half, adds up to a fall in average real wages of 10 percent.

What makes the demand for labor fall is a rise in the funds absorbed in connection with "rents" for land and natural resources. In an economic system such as our own, in which the literal renting of land and natural resource deposits plays a minor role, the absorption of funds in connection with such "rents" should be thought of ultimately in terms of a rise in the magnitude of net consumption attendant on the rise in the capitalized value of the land and natural resources. Thus, under the operation of the law of diminishing returns and an invariable money, when the supply of labor increases, wage rates decrease not only because of a larger supply of labor but also because of a smaller demand for labor, as funds are shifted away from the demand for labor, first to bidding up the capitalized value of land and natural resources and then to greater net consumption based on such greater capitalized values. Prices, of course, fall by less than wage rates on two counts: the fact that the supply of goods increases by less than the supply of labor, and the fact that the demand for labor falls.

This analysis, of course, has bearing on the destructive effects of environmentalism. It shows that policies of prohibiting or restricting the application of technological advances to land and natural resources must serve to reduce real wage rates in part by reducing the demand for labor as well as by means of holding down the increase in the supply of consumers' goods.¹⁵⁷

51. On the scarcity of labor, see above, pp. 42–45 and 58–61.
52. Although the diagram indicates that with a below-market wage, labor would be lost only by marginal employers—employers in the upper zone—the labor lost could actually be on the part of employers willing and able to pay even more than employers in the upper zone: employers having the most vital and urgent need for labor combined with the greatest ability to pay for labor. In this connection, one should recall the fact that under price controls on oil, the resulting shortage threatened the most vital and urgent uses for oil, such as the continued operation of oil rigs. On this point, see above, p. 211.
53. See above, pp. 584–585.
54. In individual cases, of course, real wages may be reduced. But to that extent, they are increased all the more elsewhere.
55. See above, pp. 584–585.
56. See above, *ibid.*
57. Evidence for this conclusion is provided by the relatively low rates of interest prevailing in Great Britain and the United States since that time, at least when the influence of inflation, taxation, and budget deficits is put to the side. For an explanation of why low rates of interest indicate a low proportion of total consumption on the part of businessmen and capitalists and a correspondingly high proportion on the part of wage earners, see below, pp. 725–744.
58. The concept of the “economic degree of capitalism” was introduced above, on pp. 478–480.
59. Passenger automobiles produced for rental car fleets, of course, are capital goods. By the same token, trucks produced for a government's post office are consumers' goods. On these points, see above, pp. 444–446.
60. For a discussion of the uniformity-of-profit principle, see above, pp. 172–173.
61. See above, pp. 132–133.
62. Most of the major elements of my analytical framework can be found in James Mill's remarkable essay *Commerce Defended* (London, 1808); reprinted in *James Mill Selected Economic Writings*, ed. Donald Winch (Chicago: University of Chicago Press, 1966) especially pp. 128–131. See also above, pp. 132–133.
63. The ratio of accumulated savings to total sales revenues, wage payments, and consumption expenditures is also of importance in the process of capital accumulation inasmuch as these ratios are largely measures of the degree of capital intensiveness in the economic system. On the significance of capital intensiveness, see below, pp. 631–632. See also below, p. 824.
64. For elaboration of this point and for the pattern of bringing

the analysis closer to the complexities of actual reality, see below, pp. 641–642.

65. See above, pp. 69–70.

66. For an explanation of what is responsible for the failure to see the role of technological progress in capital accumulation and the belief that saving alone is the source of capital accumulation, see below, p. 709.

69. *Ibid.*, pp. 864, 967.

70. For further discussion of the error of not perceiving the role of technological progress as a cause of capital accumulation and of understating the role of capital accumulation in economic progress, see below, pp. 776–778. There it will be shown that this error is present in the work of Robert Solow, the leading economic theorist of the Clinton administration, who, ironically enough, has been lauded for his alleged contributions in this area. See also below, p. 709.

71. More broadly, as pointed out earlier in this chapter in n. 63, it can be conceived of as the ratio of the total of accumulated savings relative to any of these magnitudes. Accumulated savings embrace both the value of capital in the strict sense of wealth reproductively employed and savings lent at interest to finance the purchase of consumers' wealth such as homes and personal automobiles. (On this subject, see above, pp. 449–450.) In addition, capital intensiveness can be conceived of in terms of the ratio of the total value of accumulated capital (or accumulated savings) to national income and net national product, both of which differ relatively little from aggregate consumption expenditure. For examples of such usage, see above, pp. 302 and 364, and below, pp. 759–762. See also below, pp. 699–706 and 712, which provide a demonstration both of the equality of national income and net national product and of their inherent closeness to consumption.

72. For elaboration of the role of the economic degree of capitalism and the degree of capital intensiveness in determining the ability to implement technological advances, see below, p. 824.

73. To see how the economic degree of capitalism underlies the degree of capital intensiveness, see below, pp. 725–762, which show how net consumption and productive expenditure bear on the degree of capital intensiveness. Net consumption, it will be clear, is equivalent to the difference between M and M' in the context of an invariable money.

74. For elaboration of this point, see below, pp. 682–699.

75. See above, p. 132.

76. David Ricardo, *Principles of Political Economy and Taxation*, 3d ed. (London, 1821), chap. 20; reprinted as vol. 1 of *The Works and Correspondence of David Ricardo*, ed. Piero Sraffa (Cambridge: Cambridge University Press, 1962), p. 279. Subsequent references to the Sraffa edition appear in brackets. For extensive quotations from Ricardo on the subject of capital accumulation, see below, pp. 819–820. See also, above, pp. 132–133.

77. See above, pp. 351–354 and 360–361.

78. On the contribution of free immigration to capital accumu-

lation, see above, pp. 363–364. On the contribution to capital accumulation made by the freedom of capital export, which is closely related to the freedom of immigration, see above, pp. 366–367.

79. See above, pp. 132–133.

80. Cf. above, pp. 298–299. There, the same conclusions reached in the present discussion of real wages are arrived at starting from the perspective of the benefit of private ownership of the means of production to nonowners of the means of production.

81. Concerning these last connections, see above, pp. 137–139.

82. On the uniformity-of-profit principle and its effects, see above, pp. 172–174 and 176–180. On the necessity of private ownership of the means of production for the existence of the price system, see the preceding note and, above, pp. 267–275 and 279–282.

83. See above, pp. 277–278.

84. See above, p. 299.

85. Cf. above, pp. 19–21.

86. Cf. Ludwig von Mises, *Bureaucracy* (1944; reprint ed., New Rochelle, N. Y.: Arlington House, 1969), pp. 13–14.

87. See above, pp. 98–99. The hampering of the energy industry is an example of the wider phenomenon of the environmental movement's systematic thwarting of efforts to overcome the operation of the law of diminishing returns in agriculture and mining. On this point, see above, pp. 316–317.

88. See above, pp. 178–179.

97. On these points, see T. S. Ashton, "The Standard of Life of the Workers in England, 1790–1830," in F. A. Hayek, ed., *Capitalism and the Historians* (Chicago: University of Chicago Press, 1954).

98. Once more, see above, pp. 277–278.

99. Bertrand de Jouvenel, "The Treatment of Capitalism by Continental Intellectuals," in F. A. Hayek, ed., *Capitalism and the Historians*, p. 102. While de Jouvenel's essay clearly fails as a defense of capitalism, the same cannot be said, happily, of most of the other essays in the book, notably, the introductory essay by Hayek, the two by T. S. Ashton, and the one by W. H. Hutt. These essays refute in historical terms most of the popular myths held about early nineteenth-century capitalism in England.

100. In contrast to de Jouvenel, for an accurate description of matters, see Ayn Rand, "What Is Capitalism?" in Ayn Rand, ed., *Capitalism: The Unknown Ideal* (New York: New American Library, 1966), p. 21.

101. See above, pp. 561–564.

102. On this point, see above, pp. 584–585.

103. See below, pp. 930–937.
104. See above, pp. 358–360.
105. See above, pp. 519–526.
106. See above, pp. 639–641.
107. On the role of the rate of return in limiting the degree of capital intensiveness, see below, p. 758. See also below, pp. 778–784. In connection with the operation of the law of diminishing returns, it should be realized that while the economic system as a whole can take for granted the availability of the same supply of labor, irrespective of almost any decrease in the demand for labor and increase in the demand for capital goods, the same is certainly not true for any individual firm. An individual firm that would spend less for labor and more for capital goods, would almost certainly lose a good portion of its workers to other firms, and thus would not be able to produce as much, despite its possession of more capital goods. Such considerations obviously greatly limit the demand for capital goods relative to the demand for labor.
108. Ricardo, *Principles of Political Economy and Taxation*, chap. 31 [pp. 392–393].
109. As we shall see, the same basic errors as Ricardo made on this subject are propounded in contemporary textbooks of economics in the form of the so-called balanced-budget multiplier doctrine. According to this doctrine, the government can raise the national income and the pretax income of the average citizen by virtue of raising taxes and its expenditures by an equal amount. See below, pp. 714–715.
110. For discussion of the concept of consumers' labor and all other such categories, such as producers' labor, and consumers' goods and capital goods, see above, pp. 442–447.
111. See above, pp. 591–593.
112. See above, pp. 296–310 and pp. 622–642. See also below, pp. 737–744 and 826–831.
113. See above, pp. 300–301.
114. See above, pp. 308–310.
115. To the extent that the increase in demand for labor here is accompanied by an increase in the supply of labor employed by business, the rise in wage rates is less. But then, precisely because there is an increase in the supply of labor employed by business, there is an increase in the supply of consumers' goods produced and sold and thus a corresponding fall in the general level of the prices of consumers' goods. Thus, real wages still increase.
116. See above, pp. 569–570, and below, pp. 725–736.
117. See below, pp. 725–736, especially pp. 735–736, for an understanding of how a lower rate of net consumption results in a lower rate of profit.
118. Cf. U.S. Department of Commerce/Bureau of Economic Analysis, *The National Income and Product Accounts of the United States, 1929–1976 Statistical Tables* (Washington, D. C.: U.S. Government Printing Office, 1981), pp. 23–24, 34–36, 195–196; for subsequent years, cf. *idem*, *Survey of Current Business*, especially the July issues.
119. In Chapter 9, I argued that today the consumption expenditure of the significant-sized capitalists, namely, those with a capital of \$2 million or more, is probably on the order of 5 percent of the total consumption of the economic system. (See above, pp. 302.) This is an amount that is less than 5 percent of national income to whatever extent saving out of income makes national income exceed consumption expenditure, which today is certainly not by very much. The excess of total private net consumption over the consumption expenditure of the significant-sized capitalists is accounted for by the consumption expenditure of all the smaller-sized capitalists, including, of course, wage earners in their capacity as savers who earn and consume interest.
120. See above, p. 301.
121. See above, pp. 298–300 and 636–639.
122. As the degree of capital intensiveness in the economic system increased in consequence of the reduced deprivations made upon businessmen and capitalists and their ability to save, private net consumption would show a tendency to rise (not in its rate, but simply in its absolute amount) thanks to the resulting increase in accumulated capital. To properly understand the significance of this development, one should think of it simply as the undoing of the decline in the degree of capital intensiveness of the economic system that I described in Chapter 9 as having accompanied the forcible reduction in the personal consumption of significant-sized capitalists from something on the order of 10 percent of total consumption to something on the order of 5 percent of total consumption. (See above, p. 302.) Of course, even with the restoration of private net consumption, both the distribution factor and the demand for capital goods relative to the demand for consumers' goods would continue to be substantially higher than under the policy of government deprivations and spending. It would be a question of total private net consumption increasing perhaps from its present level of about 7.5 percent of national income to about 15 percent of national income. Over the same period of time, the government's taxation of profits and interest would have fallen by approximately twice as much, leaving the difference to constitute a permanent increase in the demand for capital goods and labor by business. A further substantial permanent increase in the demand for capital goods and labor by business would result from the elimination of government budget deficits, inasmuch as the government's reduced consumption and borrowing would be accompanied by correspondingly more funds being made available to business firms with which to buy capital goods and pay wages.
123. It should be realized that only insofar as the rise in demand for labor serves directly or indirectly to raise wage rates relative to profit incomes can it serve as the basis for inducing non-wage earners to become wage earners.
124. See above, pp. 621–622.
125. See above, pp. 296–303.
126. See above, pp. 296–310 and 618–642.
127. Cf. Ludwig von Mises, *Human Action*, 3d ed. rev. (Chicago: Henry Regnery Co., 1966), pp. 840–851.
128. See above, pp. 308–310 and 618–642.
129. For elaboration of the following analysis, see my article "Are Profits Available for the Payment of Additional Wages?," *Il Politico* 29, no. 3 (June 1964), pp. 564–572.
130. See above, pp. 300–301.
131. See above, pp. 647–648.
132. See below, pp. 762–767. The present discussion presupposes knowledge of relationships that are not fully demonstrated until the first part of Chapter 16. Thus, to be fully clear, it should probably be reread after reading pp. 719–787.

133. The call for such a double payment was implicit in the previous example, inasmuch as all of the profit of \$600,000 already had its counterpart in spending for capital goods or labor.

134. Under a commodity money standard, as a by-product of this process, it also reduces the rate of increase in the supply of commodity money, which reduces both the nominal rate of profit and the rise in nominal, that is, money, wages.

135. See above, pp. 561–564.

136. See above, pp. 367–371.

137. It should be realized that unions cause lower wage rates or unemployment in complementary fields, by means of reducing the demand for the services of those fields. For example, when a carpenters' union secures higher wage rates for carpenters, it thereby increases the construction cost and thus the price of houses. This reduces the quantity demanded of houses and thus the demand for the services of plumbers, electricians, workers who produce wallboard, and so on. These groups of workers must then either suffer unemployment or accept lower wage rates as the result of the carpenters' union-imposed wage increase.

138. Less is produced insofar as the supply of goods consumers want more is held down while the supply of goods they want less is increased. Less is also produced insofar as union restrictions lead to imbalances in the supply of various complementary means of production.

Cairnes, *Some Leading Principles of Political Economy Newly Expounded* (1874; reprint ed., Fairfield, N. J.: Augustus M. Kelley, 1974), pp. 149–213; James Mill, *Elements of Political Economy*, 3d ed., rev. and cor. (1844; reprint ed., Fairfield, N. J.: Augustus M. Kelley 1965), pp. 131–135.

147. Cairnes, *Political Economy*, p. 282.

148. This is not to say that the classical economists were unaware of those elements. On the contrary, my analysis of capital accumulation as being determined both by the relative demand for capital goods and by the productivity of capital goods is based largely on their writings. See above, p. 669, n. 62, and the quotation from Ricardo on p. 634, earlier in this chapter. See also below, pp. 819–820.

149. Cf. above, pp. 491–497.

150. Cairnes, *Political Economy*, p. 283.

151. Cf. John Stuart Mill, *Principles*, pp. 992–993, where these passages appear as the entire quoted content of "Bibliographic Appendix O."

152. For a typical textbook presentation of the theory, see Samuelson and Nordhaus, *Economics*, 13th ed., chap. 27.

153. See Murray N. Rothbard, *Man, Economy, and State*, 2 vols. (New York: D. Van Nostrand & Co., 1962), 1:406–408.

154. Cf. above, pp. 200–201 and 206–209. Also cf. the lengthy quotation from Böhm-Bawerk on this point, on pp. 414–416.

155. See above, pp. 201–202 and 206–209.

156. However, see above, the preceding page, n. 107, where I indicate that the law of diminishing returns plays a major role in determining the allocation of capital between the demand for labor and the demand for capital goods.

157. Cf. above, pp. 316–317.

CHAPTER 15

AGGREGATE PRODUCTION, AGGREGATE SPENDING, AND THE ROLE OF SAVING IN SPENDING

In order to understand many crucial matters in economics, it is essential to have a clear understanding of the subject of aggregate production and aggregate spending, and of the role of saving in spending. The purpose of this chapter is to provide such an understanding. In the course of providing it, I show that what is saved is not only spent rather than hoarded, but is the source of *most* spending in the economic system, and that the greater is the degree of saving, the higher and more rapidly rising tend to be both total production and total spending as a direct result.

Of necessity, much of the discussion that follows centers on the concept of gross national product (GNP), by which is meant the total of what is produced in the economic system in any given period of time, such as, typically, a year. In this chapter, I use the traditional expressions gross national product and GNP, rather than the recently introduced expressions gross domestic product and GDP, because the authors I quote all use them. For all practical purposes, GNP and GDP are the same. The only difference is that GNP includes the economic contribution of nationals living abroad and excludes that of foreigners residing within the country, while GDP reverses this procedure.

Spending Not a Measure of Output

Before proceeding further, an important preliminary matter that must be dealt with is the fact that the total of the money which is exchanged for goods and services in the economic system is not in any sense a *measure* of the

total output of the economic system. The expenditure of money to buy any given good or service relative to the expenditure to buy any other given good or service can be taken as a measure of the *relative* amounts of wealth or production involved. For example, the expenditure of \$30,000 to buy a Cadillac, versus the expenditure of \$15,000 to buy a Chevrolet, can be taken as an indication that the Cadillac represents twice the wealth as the Chevrolet. But the total expenditure of money to buy all the goods and services produced in the economic system is not a measure of those goods and services in any sense. If, for example, the total annual output of the American economic system should sell for \$20 trillion rather than \$10 trillion, that is in no sense an indication that the production of the economic system has doubled. As was shown in Chapter 12, such a development is likely to be merely an indication that *the quantity of money* in the economic system has doubled. The quantity of money, not the physical volume of output, is the determinant of the total volume of spending in the economic system. Only under a system of commodity money, i.e., a gold or silver standard, is there any kind even of indirect connection between production and spending, and then it is only insofar as the ability to produce more or less in general results in an ability to produce more or less gold and silver in particular—i.e., only insofar as the ability to produce determines the quantity of money in the economic system. (These observations, of course, do not detract in any way from recognition of the importance of earning money and of the connection between money-

making and productive activity, which, as we have seen, are essential features of a division-of-labor society.¹⁾

The fact that the money exchanged for the output of the economic system is not a measure of that output is confirmed by the resort to price indexes in an effort to convert so-called nominal GNP—i.e., GNP in terms of mere expenditure—into a measure of output, that is, into a measure of so-called real GNP. When nominal GNP doubles, say, it is recognized that this in no sense necessarily means that total production has doubled. It may mean merely that the same amount of production is sold at twice the prices. The attempt is then made to convert nominal GNP into a measure of real GNP by means of dividing it by the rise in prices. Thus, it is held, in this particular case, because the doubled nominal GNP is offset by doubled prices, there is no rise in real GNP; but if nominal GNP should triple, say, while prices double, then, it is held, real GNP has increased in the ratio of three to two.

Shortcomings of Price Indexes

It should be realized that even the application of price indexes does not enable GNP to serve as any kind of precise measure of total production. For one thing, price indexes either make no allowance for changes in the quality of products or an allowance that is necessarily highly subjective and more or less arbitrary. Thus, for example, if one enters into a price index the price of “an automobile,” irrespective of whether it is an automobile of 1993 or 1933, one obviously omits something very important, namely, the enormous improvement in automobiles during this time. In so doing, one is led to overstate the price in the later year in comparison with the earlier year. If, however, one attempts to take into account the improvement in automobiles, any allowance one makes is necessarily highly subjective and more or less arbitrary, in that there is no way of knowing just how much more a buyer is getting for his money in 1993 in comparison with earlier years and thus no way of knowing by just how much one should adjust the price of today’s automobiles before entering it into the price index. The problem, of course, applies to practically all goods, inasmuch as the quality of almost every good changes over time, for better or for worse.

In addition, the problem arises of how to *weight* the changes in individual prices over time. Obviously a change in the price of a relatively minor good, such as carrots, on which people spend only a very small portion of their incomes, cannot be counted as heavily as a change in the price of a major good, such as housing, on which people spend a very substantial portion of their incomes. The change in the price of housing will be entered in the index with a much greater weight than the

change in the price of carrots. It will enter with a weight that is greater to the degree that the fraction of total income spent for housing is greater than the fraction of total income spent for carrots. The problem, however, is that the way the expenditure of income is divided between the different goods does not remain the same over time. The consequence is that different overall price indexes will result depending on which year’s expenditure pattern is chosen for determining the relative weights to be assigned to the different price changes. Consider for example, the different weights that must be assigned to changes in the price of personal computers and VCRs depending on whether one takes 1987 or 1977 as the base year.

These problems, of course, are problems apart from the question of converting nominal GNP into a measure of real GNP. They are problems of price indexes as such, irrespective of the purpose for which they are used. In the last analysis, it is difficult to see how the use of price indexes—and thus measures of real GNP—provide any greater actual precision than such qualitative judgments as: there is no perceptible change, there is a slight change, there is a significant change, there is a large, very large, or enormous change.

1. Gross National Product and the Issue of “Double Counting”: A Is A Versus A Is $A+$

I turn now to a subject that should be extremely straightforward and simple, but which is complicated by the most profound confusions concerning the nature of entities. Thus, while nothing should be more elementary than the fact that the axiom A is A —a thing is itself—applies to the production and purchase of commodities, it turns out that precisely this is what is more often denied than affirmed by contemporary economics. For the prevailing approach to aggregate production and aggregate spending routinely regards things as being *more than themselves*—its formula amazingly enough is that A is $A+$. For example, and this will be demonstrated at great length, it regards a loaf of bread as more than a loaf of bread—namely, as a quantity of flour, wheat, and labor services as well as a loaf of bread, and the purchase of a loaf of bread as the purchase of more than a loaf of bread—namely, as the purchase of flour, wheat, and labor services as well. The prevailing approach represents a systematic confusion between the contents of consciousness—that is, knowledge of connections between things—and independently existing physical entities. In effect, because its practitioners know that bread is made from flour and that flour is made from wheat, they lose sight of the fact that bread, flour, and wheat are distinct entities, and instead jumble them together as

though they all represented some sort of interchangeable intellectual substance. Indeed, I will show that contemporary economics holds what can only be described as a *Platonic-Heraclitean view of the nature of entities*. That is, it holds a view of entities not as being independently existing physical objects which man’s mind must grasp, but as being the *creation* of the human mind in the form of bundles of abstractions which can be put together and taken apart at will to form different entities. I call it Platonic in that it views entities as consisting of concepts or abstractions. I call it Heraclitean in that it views entities as though they represented a kaleidoscopic flux, in which a thing can simultaneously be itself and other things. This is what I mean when I say that instead of the Aristotelian formula that *A is A*—a thing is itself—contemporary economics goes by the formula that *A is A+*—a thing is itself plus more than itself.²

I will begin to make all of this clear by first presenting my own approach to the concept of gross national product.

Common-sense observation implies that the total production—the gross product—of the economic system in any given period of time, such as a year, is the total of all of the goods and services produced in that period of time. It is, for example, the sum of the bread, flour, and wheat, the automobiles, steel sheet, and iron ore, the tractors and auto plants, and all other goods and services produced in the year. (Previous discussion in Chapter 11, of course, makes it clear that in the context of a division-of-labor society, the production to be counted must be confined to production carried on for the purpose of earning money, because all other, merely physical production is, in actuality, consumption.³) This total production is obviously what should be called the gross national product.

Now much of production, of course—indeed, the greater part of it in a modern economy—is the production of means of production—capital goods—which are consumed in the process of further production. In this category fall such products as flour and wheat, and steel sheet

and iron ore, as well as the equipment and factory buildings used. All such products are productively consumed in the course of further production.⁴

When the total of productive consumption is subtracted from the gross national product, the result can appropriately be termed the net national product (NNP). Net national product, in other words, is simply gross national product minus productive consumption. Net national product represents the *gain* from production. It is the excess of what is produced over what is consumed in order to produce it, that is, over what is productively consumed.

It turns out that net national product is equal mainly to that part of gross national product which is unproductively consumed—viz., to consumers’ goods and services. This is because the part of gross national product which consists of capital goods is largely netted out in the subtraction of productive consumption. For example, the part of gross national product that is wheat is subsequently productively consumed in the making of flour; the part of the gross national product that is flour is subsequently productively consumed in the making of bread. Thus, the wheat and the flour will not be counted in the net national product, for they are subtracted from the gross national product as productive consumption in the process of arriving at net national product. Only the bread will be counted in net national product, because only it, as a consumers’ good—a “final product”—is not productively consumed in the production of further products.

The nature of gross national product, the process of productive consumption, and the distinction between gross and net national product, is illustrated with quantitative precision in Figure 15–1. In that figure, we have a succession of time periods depicting the production of x_1 bushels of wheat in *Period 1*, y_1 sacks of flour in *Period 2*, and z_1 loaves of bread in *Period 3*. The wheat of *Period 1* is productively consumed in producing the flour of *Period 2*, which in turn is productively consumed in

Figure 15–1
Gross Product and Productive Consumption

Period	Bushels of Wheat	Sacks of Flour	Loaves of Bread
1	X_1		
2	X_2	Y_1	
3	X_3	Y_2	Z_1
4	X_4	Y_3	Z_2

producing the bread of *Period 3*. In *Period 2*, a fresh supply of wheat, x_2 bushels, is produced alongside the production of y_1 sacks of flour. In *Period 3*, a simultaneous production of wheat, flour, and bread occurs, which is repeated in *Period 4* and, by implication, in all subsequent periods.

Now the *gross product of Period 3* is, of course, the sum of the x_3 bushels of wheat plus the y_2 sacks of flour plus the z_1 loaves of bread. The *net product of Period 3* is this sum minus the x_2 bushels of wheat and y_1 sacks of flour produced in the preceding period and productively consumed in *Period 3*. In exactly the same way, the gross product of *Period 4* is the sum of x_4 bushels of wheat plus y_3 sacks of flour plus z_2 loaves of bread, while the net product of *Period 4* is that sum minus the x_3 bushels of wheat and y_2 sacks of flour produced in the previous period. (In Figure 15–1, the productive consumption of any period is equal to the production of the period before insofar as the latter consists of means of further production.) And again by the principle that everything that is produced is produced, the gross product of *Periods 3 and 4 combined* is the sum of x_3 plus x_4 bushels of wheat plus y_2 plus y_3 sacks of flour plus z_1 plus z_2 loaves of bread. The net product of these two combined periods is, of course, this gross product minus the combined productive consumption of the two periods, which last is x_2 plus x_3 bushels of wheat plus y_1 plus y_2 sacks of flour.

Figure 15–1 confirms that the net product tends to equal little more than the production of consumers' goods alone. For example, if in *Period 3* the x_3 bushels of wheat produced merely equalled the x_2 bushels of wheat productively consumed, and the y_2 sacks of flour produced merely equalled the y_1 sacks of flour productively consumed, then the net product would be equal strictly to the production of the z_1 loaves of bread alone. This is because the subtraction of productive consumption would completely net out all of production beyond the production of these consumers' goods. Only to the extent that the production of capital goods is greater or less than the productive consumption of capital goods, does the net product differ from the production of consumers' goods. To the extent that x_3 bushels of wheat are greater or less than x_2 bushels of wheat, and y_2 sacks of flour are greater or less than y_1 sacks of flour, the net product of *Period 3* is greater or less than z_1 loaves by x_3 minus x_2 bushels of wheat plus y_2 minus y_1 sacks of flour.

It should be apparent that to the extent that the production of capital goods such as wheat and flour in a given period exceeds or falls short of productive consumption in that period, the stock of capital goods in existence equivalently increases or decreases. For this reason, the net product in such a case can be said to be equal to the supply of consumers' goods produced plus

this increase or minus this decrease in the supply of capital goods. Indeed, the net product equals the production of consumers' goods plus the increase or minus the decrease in the supply of capital goods in every case, even when the production and productive consumption of capital goods are equal. (In this instance, the change in the supply of capital goods that is to be added or subtracted can be taken simply as zero.)

The concepts of GNP and productive consumption that I have just presented are essentially those of the British classical economists. For example, Adam Smith writes:

Though the whole annual produce of the land and labour of every country, is, no doubt, ultimately destined for supplying the consumption of its inhabitants, and for procuring a revenue to them; yet when it first comes either from the ground or from the hands of the productive labourers, it naturally divides itself into two parts. One of them, and frequently the largest, is, in the first place, *destined for replacing a capital, or for renewing the provisions, materials, and finished work, which had been withdrawn from a capital*; the other for constituting a revenue either to the owner of this capital, as the profit of his stock; or to some other person, as the rent of his land. Thus, of the produce of land, one part replaces the capital of the farmer; the other pays his profit and the rent of the landlord; and thus constitutes a revenue both to the owner of this capital, as the profits of his stock; and to some other person, as the rent of his land. *Of the produce of a great manufactory, in the same manner, one part, and that always the largest, replaces the capital of the undertaker of the work*; the other pays his profit, and thus constitutes a revenue to the owner of this capital.⁵

The Smithian view of GNP is propounded by James Mill, another major classical economist, who states: "The whole annual produce of every country is distributed into two great parts; that which is destined to be employed for the purpose of reproduction, and that which is destined to be consumed. That part which is destined to serve for reproduction, naturally appears again next year, with its profit. This reproduction, with the profit, is naturally the whole produce of the country for that year."⁶

Indeed, there is virtually no difference between my view of the gross national product and that of the classical economists. Where I part company from them in this area is only when it comes to the question of what is to be included in the concept of productive consumption and hence in net national product. They frequently, but not always, regard the consumption of the wage earners as productive consumption, which I, of course, do not. As a result, they tend to view net national product as essentially the same as profits, while in my view, when stated in monetary terms, it includes wages as well.⁷ The important ground I share with the classical economists here is that of recognizing that the gross national prod-

uct—the total of what is produced in a country in a year—includes the production of everything: for example, flour and wheat as well as bread, and steel sheet and iron ore as well as automobiles. Compared with this point in common, any differences are minor.

Contemporary economics, on the other hand, presents a radically different view of gross national product. It presents GNP as the total output of the economic system. Yet it also claims that GNP is measured exclusively by the amount of *final* product, which means essentially just *consumers'* goods. In Figure 15–1, which shows the successive production of wheat, flour, and bread, contemporary economics would describe essentially only the bread as representing the gross national product! Essentially, only it is the final product. Contemporary economics dismisses goods such as wheat and flour as mere “intermediate products,” which are not to be counted in the gross national product.

The treatment given by Samuelson and Nordhaus is typical. “What is GNP?” they ask. And they answer, “It is the name we give to the total dollar value of the goods and services produced by a nation during a given year.”⁸ And then, four pages later, they declare, “GNP, or gross national product, can be measured . . . as the flow of final products . . .”⁹ Indeed, so as to leave absolutely no doubt about it, they emphatically declare that “GNP excludes intermediate goods, i.e., ones that are used up to produce other goods. GNP hence includes bread but not wheat, and cars but not steel.”¹⁰

Now if GNP were presented merely as the total of the final products produced in the economic system, then its measurement as such would be unobjectionable. In that case, however, it would have to be realized that what was being called gross national product was in fact a highly netted national product, that, indeed, it was virtually indistinguishable from net national product as I have described it, namely, as the gross product minus productive consumption. But this is not the procedure of contemporary economics. It advances the concept of gross national product simultaneously as the total output of the economic system—that is, as the true gross product—and as merely the final product of the economic system. Indeed, so ingrained is its confusion between total product and final product that it regards as an *error* any attempt even to express the actual gross national product! To include the wheat and the steel, according to Samuelson and Nordhaus, is to commit the error of “double counting.” “To avoid double counting,” they explain, “we take care to include in gross national product only final goods and not the intermediate goods that go to make the final goods.”¹¹ Thus, as I say, the very act of expressing the actual gross national product—the very act of saying that the total of what is produced is the

wheat and the flour as well as the bread, the iron ore and the steel as well as the automobiles—is called the error of “double counting.”

Gardner Ackley, who was Chairman of the Council of Economic Advisers under Presidents Kennedy and Johnson, expresses these views as clearly and forcefully as possible:

National product is the economy's total current output of goods and services valued at the market prices they command . . .

The main difficulties in computing national product lie in the avoidance of double counting. We should not count as output the bread, the flour that went into the bread, the wheat that produced the flour, and the fertilizer that helped grow the wheat. Despite all the steps in the process, we end up only with bread—bread is the product, not bread plus flour plus wheat plus fertilizer. In other words, we want to count only “final products,” excluding “intermediate products.”¹²

The doctrine, so clearly expressed by Ackley, that the final product *is* the total product has truly amazing implications. Ackley himself has stated one of them when he declares, “bread is the product, not bread plus flour plus wheat plus fertilizer.” True enough, bread may be all that we end up with, but bread is certainly *not* all that is produced in the course of getting to the bread. The production of the flour, wheat, and fertilizer are no less real and no less a part of total production than the production of bread; and if they were not produced, bread could not be produced. Despite the belief of contemporary economics, the production of bread does not actually represent the production of any of these things. On the contrary, in the mere act of producing bread, one not only does not produce flour, wheat, or fertilizer—one simply *consumes* flour. In order for the consumption of flour, and thus the production of bread, to be possible, there must be a production of flour. And, of course, in exactly the same way, there must be a production of wheat, to make possible its consumption, and thus the production of flour; and of fertilizer, to make possible its consumption, and thus the production of wheat. The only proper procedure is to acknowledge both the production and the subsequent productive consumption of all such “intermediate goods.”

The incredible view of contemporary economics expressed by Ackley is that *it is an error to claim that all that is produced, is in fact produced*—that to do so is to claim that *more* is produced than is in fact produced. Only the bread, we are told, is produced. According to contemporary economics, to claim that the bread plus the flour plus the wheat plus the fertilizer are produced is to overstate the actual amount that is produced.

It follows, according to this view, that such usually reliable publications as *The Statistical Abstract of the*

United States are in error. For example, the 1986 edition of that publication reports on page 596 that over seven million automobiles were produced in the United States in 1984. The same publication, on page 765, reports a separate figure of over ninety million tons for the production of raw steel in the United States in 1984. *The Statistical Abstract* clearly informs its readers that both this number of automobiles *and* this quantity of raw steel were produced in the United States in 1984. And thus, according to contemporary economics, it is guilty of the error of “double counting” and of correspondingly representing the production of the United States as greater than it actually was in 1984. For contemporary economics knows that the production of the automobiles already counts the production of steel and thus to claim that both the steel and the automobiles were produced is to double count the steel. The truth, according to contemporary economics, is that only the automobiles were produced. To paraphrase Ackley, “automobiles are the product, not automobiles plus steel.”

Thus, the contemporary concept of GNP is not only, in actuality, a highly netted-product concept, but it goes so far as to seek to *obliterate* both the production and the productive consumption of the so-called intermediate products. In so doing, its concept of total production denies the very existence of the far greater part of total production in the economic system.

What underlies the notion that the final product literally is the total product is a bizarre notion of what it is that an individual producer actually produces. According to common sense, the product of a baking company, for example, is bread; that of a flour mill, flour; that of a wheat farmer, wheat. According to contemporary economics, this is a mistake. In its view, what each producer produces is *not* his product, but *the difference* between his product and the means of production he uses up in order to produce it. Thus, a baking company does not produce bread, according to contemporary economics, but the *difference* between bread and flour; a flour mill does not produce flour, but the *difference* between flour and wheat; and similarly for a wheat farmer and any other producers who may still more indirectly help to make possible the production of bread. This notion is clearly expressed in the textbook of Prof. Lloyd G. Reynolds of Yale University, who writes:

A farmer produces \$100 worth of wheat, which is sold to a flour miller. The milling company, by adding labor and capital inputs to this raw material, produces flour which it sells for \$150. A baking company uses this flour to produce \$225 worth of food

How much has the milling company produced? Not its sales revenue of \$150, since \$100 of this was really produced by the farmer. The milling company’s output is the sales value of its product minus its purchases from the

preceding stage of production. We call this the value added at the milling stage, which in this example is \$50.¹³

It bears repeating: the milling company, according to Professor Reynolds (who speaks for the whole of contemporary economics on this point) *does not produce* “its sales revenues of \$150, since \$100 of this was really produced by the farmer. The milling company’s output is the sales value of its product minus its purchases from the preceding stage of production.” Thus, for all the world to see, we have the doctrine baldly stated that *producers do not produce their products, but the difference between their products and the means of production they consume in producing them*, and, further, that the part of their products that they may naïvely believe they produce, but allegedly do not produce, is produced by their suppliers. No other conclusion is possible when it is kept in mind that the money values involved are supposed to measure underlying physical production.

Thus, according to Professor Reynolds and contemporary economics, producers do not produce their actual physical products but conceptual differences, which represent an abstract part both of their products and of the products of their customers. The wheat farmer, for example, is alleged to produce both wheat minus fertilizer, rather than wheat, and part of the flour allegedly not produced by the milling company.

It is on the basis of viewing the product of the individual producers as conceptual differences rather than actual physical products that contemporary economics arrives at the conclusion that GNP—the *total* of production—can be measured equivalently either by the value of the final product or by the sum of the values added at each stage of production. If what the baking company produces is bread minus flour, rather than bread; and what the milling company produces is flour minus wheat, rather than flour; and what the wheat farmer produces is wheat minus fertilizer, rather than wheat; and so on, back to the remotest stages of production, then the total product of all these parties combined is, indeed, the bread alone. For in adding up the sum of such differences, all items but the bread cancel out, inasmuch as they all appear as equivalent positive and negative terms. And then, of course, the value of the bread, as the value of the final product, allegedly represents the value of all that is produced.

Now let us look at the so-called value-added approach to calculating GNP. Value added, of course, is the monetary counterpart, the alleged monetary measure, of the conceptual product difference that a producer allegedly produces in place of his actual physical product. Thus, if the product of a baker really were the difference between the bread he produces and the flour (and other previously produced means of production) he consumes in order to

produce bread, then the appropriate measure of his production would be the difference between the value of the bread and the value of the flour (and all other such inputs).

Indeed, all of this can be described in terms of a profound confusion on the part of contemporary economics between the concepts of gross and net product. Contemporary economics believes that what a producer produces is merely the *gain* entailed in the production of his product, that is, not his gross product but merely his *net* product. Thus its entire procedure can be described in terms of taking a highly destructive mental shortcut: Namely, instead of going to the trouble of recognizing that producers produce actual physical products and in the process engage in productive consumption, and that the gain from this process is the difference between their production and productive consumption, i.e., the net product, it attempts to leap directly to the net product, as though *that* were what producers produced. In the process it obliterates the very concepts of the gross product and productive consumption.

Despite contemporary economics, the fact is that each producer produces his product, neither less nor more. By this last, I mean that just as a producer's suppliers do not produce any part of his product, so he does not produce any part of the product of his customers. The wheat farmer does not produce any part of the miller's flour, and the miller does not produce any part of the baker's bread. The wheat farmer produces simply and only wheat, the flour miller, simply and only flour, and the bread baker, simply and only bread. Each party produces only his own product and the totality of his own product. (Interestingly, even contemporary economics recognizes this fact when it fails to urge against antitrust actions based on the fewness of producers, any presence of firms' suppliers as representing an addition to the number of producers. For example, in an antitrust action against baking companies based on alleged oligopoly, contemporary economics would not be found claiming the presence of tens of thousands of wheat farmers as producers of bread. Its inconsistency on this score is probably to be explained on the basis of what best serves the power of the state.)

The world of contemporary economics is indeed a strange one. By its logic, economics professors do not write books, but the difference between books and paper. When they go home to dinner, they find that their wives have not made a roast beef, say, but the difference between a cooked roast beef and a raw roast beef.

Indeed, the world of contemporary economics is stranger still. Its notion that producers produce conceptual product differences rather than their actual physical products, and that these product differences are present

in the products of their customers, ultimately in the final products, is closely bound up with the bizarre, Platonic-Heraclitean notion of the nature of entities I referred to earlier. This is because when one conceives of a final product as being the sum of the alleged product differences of a series of producers, one no longer conceives of that product as a thing that exists independently, out there in reality. Instead, one conceives of it as though it were made up of a bundle of abstractions, namely, the alleged product differences. Thus, for example, instead of conceiving of a loaf of bread simply as the entity a loaf of bread, one conceives of it as the sum of the series of abstractions bread minus flour, plus flour minus wheat, plus wheat minus zero (zero for the sake of brevity and simplicity). As soon as one does this, one is ready to conceive of one and the same given entity as though it were a multiplicity of entities.

Specifically, one is ready to conceive of the final product as though it were the total product not merely in the sense of the sum of alleged product differences or product additions, but in the sense of the sum of all of *the actual physical entities* involved. That is, for example, one is ready to conceive of bread as being bread, flour, and wheat, and, of course, to conceive of the market value of bread as constituting the market value of flour and wheat as well. Precisely these confusions are present in the conviction of contemporary economics that the value of a final product counts the value of the so-called intermediate products necessary to its production.

The mechanism by which one conceives of a final product as more than itself—as being both itself and all of the previously existing products whose production and productive consumption were necessary to its existence—is that of an improper selective focus. One selectively focuses on different possible combinations of the alleged conceptual building blocks—the conceptual product differences—that are thought of as constituting the final product, and then one sees in each such combination a distinct entity. One then concludes that the final product is itself plus each other such entity. Thus, to continue with the example of bread (ignoring all stages of production prior to wheat farming), one selectively focuses on its alleged conceptual building blocks in three alternative ways that appear to represent distinct entities:

$$(1) \text{ Bread} = [(\text{Bread} - \text{Flour}) + (\text{Flour} - \text{Wheat}) + (\text{Wheat} - \text{Zero})] = \text{Bread}$$

$$(2) \text{ Bread} = (\text{Bread} - \text{Flour}) + [(\text{Flour} - \text{Wheat}) + (\text{Wheat} - \text{Zero})] = \text{Flour} + \text{fade out}$$

$$(3) \text{ Bread} = (\text{Bread} - \text{Flour}) + (\text{Flour} - \text{Wheat}) + [(\text{Wheat} - \text{Zero})] = \text{Wheat} + \text{fade out}$$

In the first formulation one focuses simultaneously on all three of the conceptual product differences that are

regarded as constituting bread. The holding of all three together in consciousness is indicated by the use of surrounding brackets. In this case, bread is regarded as being bread, which is shown in italic type on the right-hand side of the equation.

In the second formulation, one regards bread as flour. One does this by allowing the first conceptual product difference, bread minus flour, to fade from consciousness, as indicated by its placement outside of the brackets. One then focuses on the combination of the two remaining conceptual product differences, which add up to flour. Again, the selective focus is shown by placement within brackets. The result on the right-hand side of the equation is *flour*, in italic type, plus a remainder that is altogether dismissed from consciousness and which I therefore describe as “fade out.”

Finally, in the third formulation, bread is conceived of as wheat. Here the two conceptual product differences, bread minus flour and flour minus wheat, are both allowed to fade from consciousness, and only the remaining conceptual product difference, wheat minus zero, is focused on. Once again, the fading of a product difference from consciousness is shown by its appearance outside of brackets, while the selective focus on a product difference is shown by its appearance within brackets. On the right-hand side of the equation, the result is *wheat*—plus fade out.

In this way, a loaf of bread appears as a loaf of bread, a quantity of flour, and a quantity of wheat. And, of course, it is on this basis that the value of a loaf of bread appears to count the value of the loaf of bread, the value of the flour from which it was made, and the value of the wheat from which the flour was made.

Now as I have said, this is a Platonic-Heraclitean view of the nature of entities. It is a view of entities not as being independently existing physical objects which man’s mind must grasp, but as being the *creation* of the human mind in the form of bundles of abstractions which can be put together and taken apart at will to form different entities.

It should come as no surprise to learn that the arithmetic implied by such an approach is as bad as the underlying ontology, as the example provided by Professor Reynolds clearly shows.

As we have seen in Professor Reynolds’s example, in the real world a wheat farmer produces \$100 worth of wheat, a flour miller produces \$150 worth of flour, and a baking company produces \$225 worth of bread. Professor Reynolds also includes in his example the further stage of retailing the bread to consumers for \$300. Given these assumptions, he then asks:

Now, what is the total output at all stages of production? Simply adding the sales receipts of the farmer, the miller,

the baker, and the retailer would give a total of \$775. This is clearly too large. *It counts the value of the original wheat four times, the value of the flour three times, and the value of bread twice.*¹⁴

After explaining the value-added method as the means of determining the value of the total product, Professor Reynolds continues:

There is another, simpler approach which involves only the value of final output at the point of sale. In our bread example, it’s the value of bread sold by retailers. If we use this method, *we can forget about the farmer, the miller, and the baker. Why? Because the value of their output is already included in the retail price of bread.* The method yields \$300, the same output figure as the other method [viz., the same as the value-added method] . . .¹⁵

Professor Reynolds’s conclusion, which speaks for the whole of contemporary economics, that the retail value of the bread counts the wholesale value of the bread, plus the value of the flour and the wheat, rests on the following mistaken procedure. First, the \$300 worth of bread at retail is conceived of not as the value of the independently existing entity bread, but as the sum of the values of a series of conceptual product differences, namely: \$300 worth of bread at retail minus \$225 worth of bread at wholesale, plus \$225 worth of bread at wholesale minus \$150 worth of flour, plus \$150 worth of flour minus \$100 worth of wheat, plus \$100 worth of wheat minus zero. Next, these value abstractions are taken apart and put together again in different combinations, to form the value of entities other than bread at retail, namely, the value of bread at wholesale, the value of flour, and the value of wheat. In the process, in violation of the nature of an equation, one or more of the constituent value abstractions is allowed to fade from consciousness to the point of totally disappearing from the right-hand side of the equation. Finally, the value of bread is taken as constituting the sum of a series of such botched equations, despite the fact that the individual equations exist only as mutually exclusive alternatives and thus are not properly subject to addition. I show all of this in the series of equations presented in Table 15–1.

In these equations, following my practice in the discussion of contemporary economics’ treatment of physical entities, I depict each of the constituent value abstractions within parentheses, in order to show them as the conceptual building blocks of product values that contemporary economics deems them to be. On the right-hand side of each equation, I use brackets to depict the combination of these abstractions which is currently “on bright,” as it were, that is, occupies the center of attention and thus determines the particular product value momentarily under consideration. (The particular product value is named directly below the bracketed expression.) The parenthetical expressions standing outside the brackets

Table 15-1
How Contemporary Economics Double Counts the Value of a Loaf of Bread
(and of Consumers' Goods in General)

(1)	\$300	=	[(\$300-\$225) + (\$225-\$150) + (\$150-\$100) + (\$100-\$0)]
	The value of a quantity of bread at retail		The value of a quantity of bread at retail
(2)	\$300	=	(\$300-\$225) + [(\$225-\$150)+(\$150-\$100)+(\$100-\$0)]
	The value of a quantity of bread at retail		The value of the bread at wholesale
(3)	\$300	=	(\$300-\$225)+(\$225-\$150) + [(\$150-\$100)+(\$100-\$0)]
	The value of a quantity of bread at retail		The value of the flour
(4)	\$300	=	(\$300-\$225)+(\$225-\$150)+(\$150-\$100) + [(\$100-\$0)]
	The value of a quantity of bread at retail		The value of the wheat

are the value abstractions “on dim” at the moment, that is, the value abstractions that have been allowed to fade from consciousness.

Equation (1) in Table 15-1 shows the \$300 value of a quantity of bread at retail as equal simply to the value of that quantity of bread at retail, for in this equation all four of the alleged conceptual building blocks of the value of bread are held together on the right-hand side of the equation, as shown by their placement inside of the brackets.

Equation (2) in Table 15-1 shows the value of that same quantity of bread at retail as equal to the \$75 added by the retailer plus the \$225 value of the bread at wholesale. In equation (2), only the last three of the alleged conceptual building blocks of the value of bread are held together, as indicated by their placement inside brackets. It is the sum of these which is \$225. The first conceptual building block, the \$75 added by the retailer, is placed on dim and thus allowed to fade from consciousness. Accordingly, in this equation, the value of the bread at retail is perceived by contemporary economics as representing the value of the bread at wholesale.

Equation (3) shows the value of the same quantity of bread at retail as equal now to the \$75 added by the retailer, plus the \$75 difference between the wholesale value of the bread and the value of the flour used to produce it—both of which are now placed on dim and allowed to fade from consciousness—plus, finally, the \$150 value of the flour. This last is now on “bright,” by virtue of keeping together only the last two of the alleged conceptual building blocks of the retail value of bread, which is indicated by their placement within brackets on the right-hand side of the equation. It is the sum of these

which is \$150. Thus, in equation (3), the retail value of bread is perceived by contemporary economics as representing the value of flour.

Finally, equation (4) shows the value of the same quantity of bread at retail as equal to the \$75 added by the retailer, plus the \$75 difference between the wholesale value of bread and the value of the flour used to produce it, plus the \$50 difference between the value of the flour and the value of the wheat used to produce it—all three of which are now placed on dim and allowed to fade from consciousness, as shown by their placement outside of brackets—plus, finally, the \$100 value of the wheat. Only this last is now on bright and accordingly takes center stage, as shown by the placement of its value constituent within brackets. Thus, in equation (4), the value of the bread at retail is perceived by contemporary economics as representing the value of wheat.

Now what must be understood from these equations—purely as a matter of mathematics—is that it does not follow that the value of bread at retail counts anything more than *itself*. All that one is entitled to say consistently with the principles of mathematics is that the \$300 value of bread at retail is equal to any one of four different *alternative* formulations of the same facts. It is equal to either (1) the value of the bread at retail, which is \$300, *or* (2) \$75 plus the \$225 value of the bread at wholesale, which is still \$300, *or* (3) \$75 plus \$75 plus the \$150 value of the flour, which is once again still \$300, *or* (4) \$75 plus \$75 plus \$50 plus the \$100 value of the wheat, which yet once again is still \$300.

The importance of the little word “or” between each of these formulations cannot be overemphasized. The value of the bread at retail is equal to four different

alternative formulations, each of whose existence precludes the existence of any of the other three at the same time. Thus, when the value of the bread at retail equals the value of the bread at retail, it does not in addition equal \$75 plus the value of the bread at wholesale, or any of its other possible formulations. It is equal to just one formulation at a time. And while three of these formulations may be expressed in a way which highlights components that, considered separately, appear to represent the values of other goods or of bread at the wholesale level, still nothing may actually be omitted from any of the equations. The result is that all four formulations actually continue to represent *only* the value of bread at retail. In other words, all that is present here are four different ways of expressing the value of one and the same thing, namely, the bread at retail.

This discussion should make clear that contemporary economics commits two major mathematical errors in its belief that the value of bread at retail counts all the other values. First, after expressing the same facts in four different ways, it impermissibly jettisons some of the facts—that is, in equations (2), (3), and (4), it places value abstractions on a level of such dimness, that it simply forgets all about them. It regards equation (2) not as \$75 plus the \$225 value of the bread at wholesale, but simply as the value of the bread at wholesale—forgetting all about the \$75 added by the retailer. It regards equation (3) not as \$75 plus \$75 plus the \$150 value of the flour, but simply as the value of the flour, forgetting all about the first two terms. Finally, it regards equation (4) not as \$75 plus \$75 plus \$50 plus the \$100 value of the wheat, but simply as the \$100 value of the wheat, forgetting all about the first three terms. It then compounds the error of these omissions by impermissibly adding up mutually exclusive alternatives—i.e., it adds the remaining elements of equations (2), (3), and (4) to equation (1), and reaches the conclusion that the \$300 value of bread at retail “counts” \$775 in total values. Thus, contemporary economics arrives, implicitly, at the equation

$$\begin{aligned} \$300 = & [(\$300-\$225)+(\$225-\$150)+ (\$150-\$100)+(\$100-\$0)] \\ & + [(\$225-\$150)+(\$150-\$100)+(\$100-\$0)] \\ & + [(\$150-\$100)+(\$100-\$0)] \\ & + [(\$100-\$0)]. \end{aligned}$$

It is only in this way, that the value of the bread at retail can be made to count itself, the value of the bread at wholesale, the value of the flour, and the value of the wheat.

Thus, paradoxically, as this equation makes clear, *it is contemporary economics which is guilty of the error of double counting!* It counts the final product as *more* than the final product—as itself plus all the other products

which directly or indirectly contribute to its production. It is on this basis that it concludes that to count the full actual product of the economic system is to count more than is produced. If bread alone is already bread plus flour plus wheat, then bread plus flour plus wheat is more than bread plus flour plus wheat. Indeed, when one considers it, nothing could be more obvious than that contemporary economics double counts. If one believes, as it does, that part of the product—the so-called final product—is the whole product, one must be double counting that part.

2. The Role of Saving and Productive Expenditure in Aggregate Demand

The Platonic-Heraclitean view of entities and the consequent double counting of consumers’ goods is present in contemporary economics’ notion of what constitutes total spending in the economic system. It appears to be present no less in the way the great majority of people think about the process of spending and income formation. For it is generally assumed that in buying consumers’ goods, one buys more than consumers’ goods—that one buys all the means or factors of production, however remote, which have directly or indirectly contributed to the production of the consumers’ goods one buys. (Because the expression “means of production” can be taken to refer exclusively to previously produced means of production and thus to exclude human labor, as when one speaks of “private ownership of the means of production,” it is necessary in the present context to use the expression “factors of production,” which clearly embraces labor along with capital goods.)

Indeed, the confusion is such that it is often assumed that in buying consumers’ goods, one buys, interchangeably, the factors of production that have been used up *in the past* in producing the consumers’ goods one buys, and the similar factors of production that the seller of the consumers’ goods and his suppliers will buy *in the future*, in succeeding rounds of expenditure made with the money that one spends for the consumers’ goods in question. To confuse matters even further, it is frequently assumed that in buying a given good, one buys the subsequent goods which will be produced by means of it and that in some sense one buys or pays for things that are physically unrelated to the consumers’ good one buys but that the seller buys with the money one spends in buying from him.

As examples of these confusions, it is assumed that in buying a loaf of bread, one buys the flour and wheat and the labor of bakers and millers that have been used to produce that bread, or have contributed to its production. It is also assumed that one buys the further flour and wheat and labor of bakers and millers which will produce

or contribute to the production of bread in the future, and which the baker and miller buy in subsequent rounds of expenditure with the sum of money received from one's purchase of bread. In addition, it is often assumed that the buyer of bread buys toast or a quantity of sandwiches, if such is the use he makes of the bread. And it is also frequently assumed that the buyer of bread buys or pays for things that are physically unrelated to the bread, such as the advertising and research and development outlays of the baking company, or its political and charitable contributions.

In sum, let there be knowledge of a connection between any two things, whether a causal connection in physical production or a connection by way of expenditure with the same physical units of money, and the things become fused together in people's minds, as though they were one and the same entity.

Such confusions grossly exaggerate the role of consumer spending in the economic system. They make it appear that consumption expenditure is the total of expenditure, allegedly incorporating the expenditure for capital goods and labor, which in reality is made only by business firms, with funds that are not consumed, but saved and productively expended. Moreover, the inability of people to see the role of saving and productive expenditure is compounded by a further set of confusions, which leads them to believe that saving is synonymous with hoarding. Indeed, with such an exaggerated view of the role of consumption expenditure as constituting virtually all spending, there is nothing left for the view of saving except to regard it as hoarding.

The result of these confusions is a "macroeconomics" that is not at all a macroeconomics, but an economics virtually of consumption alone. It is an economics that has virtually obliterated the role of saving and productive expenditure, in the conviction that all economic activity is incorporated essentially just in consumption. It is an economics fully geared to the Keynesian fantasy world in which one not only can eat one's cake and have it too, but in which one bakes one's cake in the very act of eating it.

The purpose of the present section is to set matters right by showing the enormous role of saving and productive expenditure in the generation of aggregate demand—a role which far exceeds that of consumption expenditure in size and in most respects is more fundamental than that of consumption expenditure. As an important part of this assignment, it will be necessary to present a system of aggregate economic accounting that, unlike contemporary national income accounting, reflects the full volume of production and the full volume of spending that takes place in the generation of revenue or income. This will be done in Section 3 of this chapter.

The Demand for A Is the Demand for A

The first point that must be driven home by all possible means is the proposition that *the demand for A is the demand for A*—that is, that the demand for any concrete good or service is simply and only a demand for that concrete good or service; that in buying anything, all that one buys is that which one agrees to receive from the seller and *absolutely nothing else*.

The plain fact is that in buying a loaf of bread, one buys neither a quantity of flour, nor a quantity of wheat, nor the labor of a baker, nor the labor of a miller, nor a loaf of toast, nor anything else but a loaf of bread. One buys simply and only a loaf of bread, and not anything which has contributed to its production, nor anything which the seller of the bread may subsequently buy and which may thus contribute to the production of bread in the future, nor anything into which the bread itself may subsequently be made. Nor does one make the seller's political or charitable contributions. The purchase of any and all of these items is fully as much distinct from the purchase of a loaf of bread as these items themselves are physically distinct from a loaf of bread. Their purchase is something totally separate from and *in addition to* one's purchase of a loaf of bread.

It is necessary to explain and illustrate this proposition even to the point of belaboring it, because apparently nothing less will suffice to establish it in the minds of most people. Well over a century ago, John Stuart Mill advanced the essentially similar proposition that "demand for commodities is not demand for labour." His exposition was both clear and, unfortunately, highly prophetic in its recognition that the proposition "is, to common apprehension, a paradox" and thus "greatly needs all the illustration it can receive." Mill deserves to be quoted at length on this subject:

We pass now to a fourth fundamental theorem respecting Capital, which is, perhaps, oftener overlooked or misconceived than even any of the foregoing. What supports and employs productive labor, is the capital expended in setting it to work, and not the demand of purchasers for the produce of the labour when completed. Demand for commodities is not demand for labour. The demand for commodities determines in what particular branch of production the labour and capital shall be employed; it determines the *direction* of the labour; but not the more or less of the labour itself, or of the maintenance or payment of the labour. These depend on the amount of the capital, or other funds directly devoted to the sustenance and remuneration of labour. . . .

This theorem, that to purchase produce is not to employ labour; that the demand for labour is constituted by the wages which precede the production, and not by the demand which may exist for the commodities resulting from the production; is a proposition which greatly needs all the illustration it can receive. It is, to common apprehension, a

paradox; and even among political economists of reputation, I can hardly point to any, except Mr. Ricardo and M. Say, who have kept it constantly and steadily in view. Almost all others occasionally express themselves as if a person who buys commodities, the produce of labour, was an employer of labour, and created a demand for it as really, and in the same sense, as if he had bought the labour itself directly, by the payment of wages. It is no wonder that political economy advances slowly, when such a question as this still remains open at its very threshold. I apprehend, that if by demand for labour be meant the demand by which wages are raised, or the number of labourers in employment increased, demand for commodities does not constitute demand for labour. I conceive that a person who buys commodities and consumes them himself, does no good to the labouring classes; and that it is only by what he abstains from consuming, and expends in direct payments to labourers in exchange for labour, that he benefits the labouring classes, or adds any thing to the amount of their employment.¹⁶

Inasmuch as Mill's own exposition has passed entirely over the heads of his readers, it is necessary to advance a series of arguments in favor of the proposition that the demand for *A* is the demand for *A*, that is, in Mill's words, actually to give the proposition "all the illustration it can receive."

i. Shadow Entities and Shadow Purchases

The influence of the Platonic-Heraclitean view of entities leads people to believe such a thing as that the buyer of a loaf of bread is a buyer of flour and wheat, and the labor of bakers and millers, because it leads them to believe that these inputs *physically exist in the loaf of bread* and thus that its purchase is also their purchase. Such a view, however, has absolutely no connection with the facts of reality and contradicts the law of identity.

If I wish to buy a loaf of bread *and* a sack of flour *and* a quantity of wheat, I must buy three separate and distinct items: the bread, the flour, and the wheat. Indeed, I can see myself actually going down the various aisles of a supermarket and picking up from the shelves a loaf of bread, a bag of flour, and, if there is an extensive-enough "health foods" section, a quantity of wheat stalks. My action is very different than if I buy merely a loaf of bread alone. In the one case, I have three items in my shopping cart when I reach the checkout stand, and I pay a sum of money for each of them—one for the bread, another for the flour, and a third for the wheat. I then receive into my possession the bread, the flour, and the wheat. In the other case, I have only one item in my shopping cart—the bread—and when I reach the checkout stand, I pay a sum of money only for the bread and receive into my possession only the bread. If I buy a loaf of bread alone, I do not obtain flour and wheat in addition, or pay out the additional sums required to obtain flour and wheat. The

flour and wheat I am nevertheless still supposed to purchase in the mere act of buying a loaf of bread represent, therefore, purchases of a very peculiar kind: they are purchases which cost me absolutely nothing, and purchases which bring into my possession absolutely nothing. In a word, they are purchases which simply *do not exist!* The only entity I purchase is a loaf of bread, and a loaf of bread is neither flour, nor wheat, nor anything else but a loaf of bread. Indeed, people must dwell in a world of shadows and apparitions if they believe that they obtain bread, flour, and wheat all for the price of the bread alone, all compressed within the wrapper of the bread, and—for many perhaps, best of all—all for the same calories as are present in the bread alone.

Excuse me. Did I imagine *eating* flour and wheat? That is what those who are deluded by the Platonic-Heraclitean view of entities must believe they eat when they eat bread. In their view, they obtain flour and wheat when they buy bread and so they must believe that they eat flour and wheat when they eat bread. They should stop and think what it would be like *actually* to eat flour or wheat. I can hear someone now, sputtering and coughing as he gets a mouthful of powdery flour when he takes a bite of bread, or expressing shock and anger when he realizes he is chewing on a stalk of wheat that has managed to find its way into his slice of bread. I can hear the furious denunciations of the baking company for being so incompetent as to allow such things to happen.

If the prospect of eating flour and wheat does not give pause, then one should consider what it would be like to eat fertilizer or tractor parts, which are also supposed to be contained in bread because they have been used to help produce it and which, if bought in the act of purchasing bread, must be eaten in the act of eating bread.

Incredibly, such prospects are unlikely to daunt many of today's alleged economists. For example, Prof. George Leland Bach, who at the time was a professor of economics at Stanford University, wrote in his widely used textbook: "For example, in converting the iron ore to steel above, Bethlehem adds something to the value of *the product it passes along.*"¹⁷ The unmistakable meaning of this statement is that a steel company passes along iron ore in the steel it sells—that *somehow steel is physically still iron ore*. Similarly, Professors Alchian and Allen declare in their textbook: "For example, most steel bought from U.S. Steel by General Motors is not at that time bought by the final user, for General Motors later resells the steel as an automobile."¹⁸ In these passages, we have the baldly stated view that entities are the means of production that have been used up producing them—that automobiles are the steel sheet from the steel mills and, indeed, iron ore, and that *that* is what automobile owners drive.

Indeed, the logic of confusing one thing with another merely because the one was used to produce the other, or merely because the matter that was present in the one now shows up in the other, implies such absurd propositions as that *ice is in steam* and *ice heats houses*. For consider. If a quantity of ice is melted into water, and then the water is boiled into steam, then on the same logic as that the wheat and flour are “in” the bread and are eaten when the bread is eaten, and that the iron ore and steel sheet are “in” the automobile and are driven when the automobile is driven, it follows that the ice is in the steam, and that ice heats houses when steam heats houses.

ii. *The Need for Capital*

If the demand for consumers’ goods really were a demand for factors of production, then one would have to explain why it is necessary to possess capital before starting any business undertaking. Why, if the demand for consumers’ goods is a demand for factors of production, is it not possible for every individual who should happen to be so inclined, to set up his own steel company or railroad line? If it really is the consumers rather than businessmen who pay for the factors of production, then why can’t a prospective entrant into any line of business simply tell the workers he wants to hire and his prospective suppliers that they will be paid by the consumers of the products he will ultimately make possible, and thus should not bother him with their claims?

The truth is, of course, that before entering into any business operation, one must possess the funds required for the purchase of the necessary factors of production, for which purchases one will only *subsequently* be compensated by one’s customers. These funds, of course, are the capital the firm needs and without which it cannot proceed.

Indeed, for the most part, the customers of business enterprises are *other business enterprises*. And all those business enterprises which sell to other business enterprises not only require capital of their own, but are dependent upon their *customers possessing capital*. Such enterprises are not even compensated by the consumers for their outlays, but only by other business enterprises, out of capital. The consumers compensate only those business enterprises for their outlays with which they themselves deal.

iii. *Buying the Inputs OR Buying the Output*

A further proof that in buying from a business one does not buy what the business buys is the fact that if one really did buy what the business buys, one would not be a customer of the business—certainly not in that transaction. If, for example, one really did buy flour and labor to bake bread, then one would *not buy bread*—certainly

not the bread made from that flour, by that labor. A real buyer of flour and the labor of a baker, compelled to buy bread that is baked from that flour by that labor, would be the victim of a robbery, for he would be forced to buy his own property! His position would be that of being presented with a check for a meal cooked in his own home, by his own housekeeper, with food he himself has paid for. In buying the flour and the labor of a baker, one obtains a natural and a legal title to the bread. One owns the bread by virtue of having bought the flour and the labor. One cannot then be asked to buy the bread.

The principle that follows is that if one really does buy the inputs, one does not buy the output. If one buys the output, it is precisely because one has *not* bought the inputs.

There is a further difficulty with the confusion that in buying the output one buys the inputs. This is the problem that the demand for the inputs—the demand for the factors of production—is a productive expenditure, while if the output is a consumers’ good, the demand for the output is a consumption expenditure. In such cases, to claim that the demand for the product is a demand for the factors of production, is to claim that an expenditure which is *not* for the purpose of making subsequent sales—namely, the consumption expenditure which is the demand for the output—is an expenditure for the purpose of making subsequent sales—namely, the productive expenditure which is the demand for the inputs. Thus, it is to claim that one and the same expenditure is and is not a consumption expenditure, and is and is not a productive expenditure.

The Demand for Consumers’ Goods and the Demand for Factors of Production as Competing Alternatives

It should now be clear that the demand for consumers’ goods is not a demand for the factors of production—viz., capital goods and labor—which were employed in the past in making the production of today’s consumers’ goods possible. The purchase of those factors of production was made in the past, by the current sellers of today’s consumers’ goods and by their suppliers and by a chain of still earlier suppliers. It should be equally clear that the demand for consumers’ goods is also not a demand for the factors of production which will be employed in the future, in making possible the production of possibly similar consumers’ goods, and which will be purchased with sums of money received from the buyers of consumers’ goods in the present. These factors of production too are purchased not by the consumers but by the sellers of today’s consumers’ goods and by their suppliers and a chain of further suppliers. Indeed, once the confusions instilled by the Platonic-Heraclitean view of entities fall

away, one can see that the demand for consumers' goods is not only not a demand for factors of production, but is *in competition* with the demand for factors of production.

By this, I mean that to the extent that an individual consumes, he makes *impossible* the purchase of factors of production. This is because one can buy *either* consumers' goods *or* factors of production, but not both with the same money. Given the quantity of money in the economic system and thus the total ability of people to spend money, a high consumption is most decidedly not the precondition of a high demand for factors of production. If the demand for factors of production is to be high, consumption must be low. For every capitalist or prospective capitalist is faced with the following alternative: He can spend his funds either on consumers' goods *or* on capital goods, but he cannot, for example, buy a personal automobile *and* a truck for his business with the same money. He can spend his funds in the purchase of consumers' goods for his own enjoyment *or* he can pay the wages of workers who will render services in his business enterprise, and who will consume in his place, but he cannot, for example, buy a vacation *and* employ a machinist with the same money.¹⁹

To demonstrate as clearly as possible that the demand for consumers' goods is in competition with and at the *expense* of the demand for capital goods and labor by business enterprises, I will show how the demand for consumers' goods is capable of rising to the point of totally eliminating the demand for capital goods and labor by business enterprises. Thus, let us make the drastic assumption not only that wage earners consume the full amount of their wages but also that businessmen and capitalists, who sell goods and services, use the full amount of their sales receipts to make purchases for their own consumption. In effect, they pay themselves dividends equal to their sales receipts and go out and consume the proceeds. And to close off every last corner, let us also explicitly assume that those who introduce new and additional money into the economic system—that is, gold and silver miners as far as a precious metal standard prevails, and the government and banking system as far as such a standard does not prevail—use the new and additional money exclusively for consumption or to support consumption. In such a case, there would simply be no source of a demand either for capital goods or for labor by business firms. Whatever funds anyone took in from the sale of consumers' goods would be expended in buying further consumers' goods, or consumers' labor, and there would be nothing left with which to buy capital goods or producers' labor. Precisely this is the situation, described in Chapter 11, that prevails in Adam Smith's "early and rude state of society" and under Marx's "simple circulation."²⁰

Of course, many will probably still object that the rise in consumption envisioned in this case will place additional funds in the hands of the industries producing consumers' goods, and that because of this, these industries will be enabled to make a greater demand for factors of production than before. But this objection is absolutely wrong. It fails to take into account that we are assuming a rise in the consumption of *businessmen and capitalists*, and that this includes the consumption of the businessmen and capitalists faced with the additional demand for consumers' goods—that, indeed, we are assuming that such businessmen and capitalists, along with all other businessmen and capitalists, consume the full amount of their sales receipts. Thus, there could not only be no increase in the demand for factors of production coming from the industries producing consumers' goods, but the demand for factors of production coming from those industries would actually fall to zero. Not only would each recipient of additional consumer sales receipts simply reexpend all of the additional sales receipts in the purchase of further consumers' goods, but he would also expend in the purchase of consumers' goods the equivalent of all the funds he had previously expended in any given period in the purchase of factors of production. Thus the demand for factors of production emanating from the consumers' goods industries would be zero, despite the rise in the sales receipts of the consumers' goods industries.

It is no objection to the assumption that the demand for consumers' goods rises to the point of totally eliminating the demand for factors of production, to point out that the production of consumers' goods would then also be almost totally eliminated. For example, it is certainly true that if the demand for the means of producing personal automobiles fell to zero, no personal automobiles could be produced, no matter how high the demand for personal automobiles became. If the assumption actually held that there was only a demand for consumers' goods and no demand for factors of production, it would certainly be an incalculable disaster. In that case, no consumers' goods beyond the crudest and most primitive type could be produced, and they, in the most meager quantities. But this is the conclusion to which one comes *by way* of the proposition that the demand for consumers' goods is only a demand for consumers' goods and not a demand for factors of production. It cannot be grounds for attacking that proposition. (What would happen under such conditions is that the division of labor would revert to the most primitive level. The production of products requiring any significant degree of time and temporal succession of producers would become impossible.²¹)

Nor is it correct in this context to say that producers

who expend their entire sales receipts in their own consumption must disappear from the market. If all producers acted this way, then the fact that their products were primitive and few would not be sufficient to drive them out of business, because their competitors would not offer anything better.

Now not only would a rise in consumption spending in the enormous dimensions I have assumed mean a total elimination of the demand for factors of production, but every rise in consumption spending means a fall in the demand for factors of production or, as a minimum, a lesser increase in the demand for factors of production. For even when the quantity of money in the economic system and thus the total ability of people to spend money increases, making it possible for both the demand for consumers' goods and the demand for factors of production to increase together—even then, the principle holds. This is because the increase in the demand for factors of production would be greater still, if the increase in the demand for consumers' goods were less. (The same point applies, of course, to increases in the total volume of spending made possible by decreases in the demand for money for holding.)²²

In dealing with less drastic increases in consumption spending—that is, increases in consumption spending not so great as to eliminate the demand for factors of production altogether—it continues to be necessary to keep in mind that a rise in consumption spending does not constitute an increase in the demand for any category of goods but consumers' goods. It does not increase the total demand for goods in the economic system, but merely changes the composition of that demand. Other things being equal, a rise in the demand for consumers' goods is accompanied by an equivalent fall in the demand for capital goods. And in the course of a rise in the overall demand for consumers' goods, the additional demand for many individual consumers' goods is made possible only by an equivalent reduction in the demand for other consumers' goods. Thus, for example, in order for businessmen and capitalists to pay themselves larger dividends and thus increase their expenditure for consumers' goods, they must reduce their expenditure for capital goods and producers' labor. The only effect this has on the demand for goods as such is to increase the demand for consumers' goods and equivalently to decrease the demand for capital goods, and, within the demand for consumers' goods, to increase the demand for those consumers' goods which may happen to be favored by businessmen and capitalists, and to decrease the demand for those consumers' goods which may happen to be more commonly purchased by wage earners. That is to say, a rise in consumption spending on the part of the businessmen and capitalists will, for example,

increase the demand for personal automobiles at the expense of the demand for trucks for business purposes, and, within the demand for personal automobiles, increase the demand for Cadillacs, say, and decrease the demand for Chevrolets, say. Thus, there is no increase in the total, economy-wide demand for goods as such brought about by a rise in the consumption of businessmen and capitalists, but, as I say, a decrease in the demand for capital goods, for the labor employed by business enterprises, and for the consumers' goods the employees of business firms would otherwise have purchased. The same is true in principle of all increases in consumption, because they are always at the expense of saving and productive expenditure and thus at the expense of the demand for capital goods and producers' labor.

It is necessary to clear up the confusion caused by the fact that short of every seller using the whole of his sales receipts to consume, an increase in the demand for any product by consumers tends to result in an increase in the demand for factors of production by the producers of that product. Thus, for example, if wealthy businessmen decided to withdraw funds from their firms in order to consume in the form of buying yachts, say, the effect would normally be to cause an increase in the demand for factors of production by the yacht-building industry. Nevertheless—and this is the essential point—the *total* demand for factors of production in the economic system would now be less.

For had the businessmen not withdrawn the funds in question to buy yachts, the funds would have been used to buy capital goods, such as various types of machinery or factory buildings, and to pay the wages of workers, who would have bought various consumers' goods. The demand for *these* goods—capital goods and the consumers' goods the wage earners would have bought—does not exist as the result of the use of funds to buy the yachts. Thus the demand for factors of production that would have been made in their production is not made. But it is not the case that all that happens is a shifting of demand for factors of production from the production of these goods to the production of yachts. There is *less* demand for factors of production in the economic system as a whole. There is less precisely to the extent that the demand for yachts, a consumers' good, takes the place of a demand for capital goods and labor by business.

In quantitative terms, let us imagine that the new and additional annual yacht purchases of businessmen are \$1 billion. To make matters as simple as possible, let us further imagine that these yacht purchases come entirely at the expense of the demand for capital goods. To make matters even more simple, let us assume that they come at the expense specifically of \$1 billion worth of tanker purchases. We can readily imagine that as the result of

having \$1 billion of additional sales each year, an additional demand for factors of production now takes place every year on the part of the yacht-building industry, in the amount of \$900 million, say. However, we are entitled to assume that over and against this additional \$900 million of demand for factors of production by the yacht-building industry, there is a \$900 million per year reduction in the demand for factors of production on the part of the tanker-building industry. Thus, as far as the yacht-building consumers' goods industry is concerned, the demand for factors of production has increased by \$900 million. As far as the tanker-building capital goods industry is concerned, the demand for factors of production has decreased by \$900 million. The overall situation, however, is by no means mutually offsetting or neutral with respect to the demand for factors of production. This is because the outstanding fact of the case is that the demand for capital goods—the tankers—is less by \$1 billion and the demand for consumers' goods—the yachts—is greater by \$1 billion. Thus, overall and on net balance, the demand for capital goods is down by \$1 billion as the result of the demand for consumers' goods being up by \$1 billion.

Obviously, nothing of significance depends on the assumption that the demand for yachts increases specifically at the expense of the demand for tankers. The capital goods could be of any kind: factory buildings, machines, materials, etc., of whatever description. Nor does anything of significance depend on the assumption that the entire reduction in the demand for factors of production is at the expense of the demand for capital goods. We might imagine that part of it is at the expense of the demand for labor by business. Thus, for example, if \$500 million of the funds required for the purchase of the yachts had come from the demand for labor rather than from the demand for capital goods, the demand for factors of production as such would still have fallen by \$1 billion. The only complication introduced would have been that the reduction in the demand for labor would in turn have caused a reduction in the demand for consumers' goods on the part of wage earners and thus that part of the decline in the demand for factors of production offsetting the rise in the demand for factors of production by the yacht-building industry would have been in those consumers' goods industries rather than in capital goods industries.

What the tanker example is especially suited for illustrating is the effect of a rise in the demand for consumers' goods at the expense of the demand for factors of production, on the economic system's subsequent ability to produce. Because yachts have been produced instead of tankers, the result is simply that production in future years will have to take place without the aid of the tankers and will therefore be less. The tankers would have con-

tributed to production in the future; the yachts do not. Of course, this effect on the future ability to produce applies to every increase in the production of consumers' goods at the expense of the production of capital goods, as we well know from the last chapter. It would apply equally if the production of the yachts had been at the expense of any kind of factory or office buildings, machines or tools, or materials or components purchased by business firms, rather than specifically tankers. The increase in the production of consumers' goods at the expense of the production of capital goods always means an undermining of the ability to produce in the future.

It should go without saying that the reduction in aggregate productive expenditure that results from a rise in consumption expenditure also operates to reduce the magnitude of nominal capital in the economic system, inasmuch as nominal capital is the reflection of a series of current and prior productive expenditures. Thus while the yacht-building industry in our example attracts additional capital as the result of the rise in demand for yachts, the total capital of the economic system diminishes. The yacht-building industry does not attract as much additional capital as the rest of the economic system loses in the process.

It may be helpful to put all this in slightly different words: Namely, while every demand for goods—consumers' goods or capital goods—attracts capital and to that extent underlies an expenditure for factors of production, the amount of capital available to be attracted and the magnitude of the expenditure for factors of production that corresponds to any given demand for goods is the less, the more frequent and the larger in size is the choice of individuals to spend their funds on consumers' goods rather than on factors of production.²³ A rise in the demand for consumers' goods at the expense of the demand for factors of production increases the proportion of the demand for factors of production that is made by the consumers' goods industries while reducing the overall size of the demand for factors of production in the economy as a whole. With a big enough rise in consumption and fall in demand for factors of production, even the expenditure of the consumers' goods industries for factors of production falls and, indeed, can completely disappear, as we have seen.

Now it is certainly possible that some businessmen and capitalists who decide to step up their consumption at the expense of their capitals and demand for factors of production might merely put sales revenues into the hands of other businessmen and capitalists who choose to consume more modestly and to make a correspondingly greater demand for factors of production relative

to their sales revenues. To the extent that this is the case, then the rise in the consumption of businessmen and capitalists is only passing, and disappears as soon as greater wealth comes under the control of those businessmen and capitalists who employ a relatively smaller proportion of their sales revenues in their own consumption. This circumstance, however, in no way affects the truth of the statement that consumption and the demand for factors of production move in opposite directions. For when the consumption of businessmen and capitalists rose in this case, the demand for factors of production would still fall, and only then, when the consumption of businessmen and capitalists once again declined, would the demand for factors of production return to its former level.

I do not want to be perceived as condemning in any way the purchase of yachts or any form of private luxury consumption that takes place under capitalism. Given the security of property that prevails under capitalism and the enormous degree of rationality and future orientation, such consumption takes place in a context of a far greater degree of provision for the future and capital intensive-ness of production than under any other imaginable economic system. I chose the example merely in order to make the principle clear that consumption and demand for factors of production are opposites. Furthermore, it is important always to keep in mind that while a further decline in consumption relative to the demand for factors of production can always achieve further economic improvement, it can do so *only if it is uncoerced*. If the attempt were made to force businessmen and capitalists to restrict their consumption, they would lose the incentive to accumulate and maintain their capital, which would result in far greater economic loss than could possibly be gained by any restriction that might be imposed on their consumption.²⁴ The only truly destructive consumption expenditure that exists under capitalism (or, more correctly, under a mixed economy) is the wasteful consumption of a government that is no longer confined within the limit of its proper functions. The reduction or, better still, the total elimination of such consumption can represent an enormous economic gain in bringing about a higher relative production of capital goods and a higher demand for labor relative to the demand for consumers' goods.²⁵ Indeed, even the seeming beneficiaries of such consumption expenditure must end up being better off without it, when they support themselves through their own work and saving in the midst of a society characterized by economic progress.

Compatibility With the Austrian Theory of Value

It should not be thought that the proposition "the demand for A is the demand for A" or, what is virtually

equivalent, John Stuart Mill's proposition "the demand for commodities is not demand for labour," is incompatible with the so-called Austrian theory of value, according to which the prices of factors of production are ultimately determined by the prices of the consumers' goods they help to produce. The proposition is perfectly compatible with the Austrian theory of value. The reconciliation consists in the fact that the value of factors of production *relative to one another* is determined by the value of their products, ultimately consumers' goods, relative to one another, but that the value of factors of production *relative to the value of their products* is not determined by the value of their products. This is simply to say, for example, that insofar as the factors of production in question are specific and cannot be transferred between uses, the means of producing wine will be more valuable than the means of producing bread to the degree that wine is more valuable than bread; but a rise in the total value of wine, bread, and consumers' goods in general can never mean a rise in the value of the means of producing them, if there is no change on the side of money. On the contrary, if there is no change on the side of money, every rise in consumption must mean a corresponding *fall* in the demand for and total value of the factors of production.

There is nothing surprising in this. When the Austrian theory of value declares that the value of consumers' goods determines the value of the means of producing them, it is always on the assumption—either implicit or explicit—that the relationship between the value of the products and the value of the factors of production can be ignored. However, this relationship cannot be ignored when we turn to the theory of profit and interest and the concomitant question of what causes the value of products regularly and consistently to *exceed* the value of the factors of production. Then the problem is no longer one of the value of factors of production relative to each other, but *relative to the value of their products*. And here, a rise in consumption increases the margin between the value of products and the value of the means of producing them—viz., it operates to raise the rate of profit and interest.²⁶ The Austrian theory of value, logically considered, should be taken to mean no more than that the relative value of consumers' goods determines the relative value of the means of producing them, and this, insofar as the factors of production are specific, that is to say, not substitutable for one another in the different uses in question. As Mill himself put it, "The demand for commodities determines in what particular branch of production the labour and capital shall be employed; it determines the *direction* of the labour . . ." To the degree that labor (or other factors of production, such as land) cannot be changed in its "direction," or cannot be

changed without some loss of efficiency, then changes in the relative value of the factors of production result.

Application to the Critique of the Keynesian Multiplier Doctrine

The proposition that the demand for *A* is the demand for *A* has major application to the critique of the Keynesian “multiplier” doctrine, a doctrine that is expounded in virtually every contemporary textbook that deals with “macroeconomics.”²⁷

The multiplier doctrine claims that an initial increment of net investment, government spending, or any other “autonomous” expenditure is followed by successive rounds of consumption spending which serve to produce a multiple increase in national income. The proposition that the demand for *A* is the demand for *A* shows that the only incomes that could be raised by the successive rounds of consumption expenditure envisioned by the multiplier doctrine would be *profits*, not wages. As should now be clear, any rise in wages, in the demand for goods at wholesale, or in the demand for capital goods of any kind depends on what is not consumed, but saved and productively expended. This is because consumption expenditure is merely consumption expenditure. It does not incorporate productive expenditure. The demand for goods at wholesale, for materials and machinery, and for labor by business is possible only to the extent that people do *not* consume but save and productively expend. Yet the Keynesians regard saving as a “leakage” and as allegedly diminishing the amount of subsequent incomes.

It is only on the basis of utterly illusory, nonexistent, shadow purchases of the kind described earlier in this section that the Keynesians can believe that additional expenditure by consumers for the goods and services of business constitute an additional demand for the labor and other inputs bought by business. Moreover, unlike other economists who have never grasped Mill’s proposition and its implicit call for the application of the law of identity to economics, the Keynesians have no escape route. They cannot claim that what they really mean when they propound the multiplier doctrine is only that an inflation-financed rise in consumer demand results in a rise in the demand for labor and other factors of production because business enterprises will spend their additional sales revenues in buying factors of production. The Keynesian analysis explicitly argues that income is raised insofar as the additional incomes corresponding to the additional sales revenues are consumed, i.e., are *not* spent for business purposes, and that the rise in incomes will be the greater, the higher is the “marginal propensity to consume” and the lower is the “marginal propensity to save.”

Samuelson and Nordhaus propound the Keynesian doctrine in unmistakable terms. They state:

No proof has yet been presented to show that the multiplier will be greater than 1. But the discussion up to now indicates how, when I hire unemployed resources to build a \$1000 woodshed, there will be a *secondary* expansion of national income and production, over and above my *primary* investment. [Expenditure for a personal woodshed, of course, is consumption, not investment. But no matter.] Here is why.

My carpenters and lumber producers will get an extra \$1000 of income. But that is not the end of the story. If they all have a marginal propensity to consume of $\frac{2}{3}$, they will now spend \$666.67 on new consumption goods. The producers of these goods will now have an extra income of \$666.67. If their MPC is also $\frac{2}{3}$, they in turn will spend \$444.44 or $\frac{2}{3}$ of \$667.67 (or $\frac{2}{3}$ of $\frac{2}{3}$ of \$1000). So the process will go on, with each new round of spending being $\frac{2}{3}$ of the previous round.

Thus an endless chain of *secondary consumption responding* is set in motion by my primary \$1000 of investment spending. But, although an endless chain, it is a dwindling chain. And it eventually adds up to a finite amount.

Upon summing up this infinite series, Samuelson and Nordhaus conclude:

This shows that, with an MPC of $\frac{2}{3}$, the multiplier is 3, consisting of the 1 of primary investment plus 2 extra of secondary consumption responding.

The same arithmetic would give a multiplier of 4 if the MPC were $\frac{3}{4}$, for the reason that $1 + \frac{3}{4} + (\frac{3}{4})^2 + (\frac{3}{4})^3 + \dots$ finally adds up to 4. . . . In other words, the greater is the extra consumption responding, the greater the multiplier. The greater the MPS “leakage” into extra saving at each round of spending, the smaller the final multiplier.²⁸

Samuelson and Nordhaus are utterly unaware that the overwhelmingly greater part of any income that could possibly be increased by virtue of the process they have described would be *profit* income. That is the only income that is earned on additional business sales revenue, and business sales revenue is the only receipt that private consumption spending generates (apart from some minor demand for domestic servants). It is also the only receipt that is generated by investment spending insofar as investment spending is for such things as the purchase of the lumber they assume in their example. Thus, for example, if I take \$1,000 and go into a shopping mall and spend it in buying clothes, say, my expenditure is \$1,000 of sales revenue to the seller of the clothes. The only income earned on those sales revenues is profit, not wages. (Readers who know anything about accounting should be sure to read the next paragraph.) If the seller of the clothes then decides to consume \$666.67 of his supposed \$1,000 of additional income, say, by going elsewhere in the mall and buying dishes for that sum,

then there is \$666.67 of additional sales revenue to the seller of the dishes. Again, any additional income earned is profit, not wages. If the seller of the dishes, in turn, decides to consume \$444.44 of his supposed additional income of \$666.67, say, in buying shoes, then once again there is only additional business sales revenue, on which the only income that is earned is profit, not wages. In this case, carrying the process to n stages, the effect of the “multiplier”—if it actually existed—would be that the \$1,000 of initial additional spending would bring about \$3,000 almost entirely of additional sales revenues and hardly any additional wage income. If the additional sales revenues represented equivalent additional net income, the only additional net income they could represent would be *profit* income, not wages. The only additional wage income would be insofar as the original investment expenditure entailed the payment of wages as opposed to the purchase of capital goods.²⁹

(In the interest of accuracy, I must point out that in reality, the amount of profit income earned on my \$1,000 of expenditure would be less than \$1,000 to the extent that the seller had to deduct additional cost of goods sold from his additional sales revenues. The incurrence of additional cost of goods sold, as I will show later on, represents disinvestment, and would actually work to undercut any actual net investment which might have launched the alleged spending chain.³⁰ In order for my \$1,000 of expenditure to constitute \$1,000 of additional profit income, we must assume that the seller sells exactly the same total physical volume of goods he otherwise would have sold in the accounting period, but now, thanks to my spending of this \$1,000, he does so for \$1,000 more of sales revenue. On this assumption, my expenditure of \$1,000 would constitute an additional profit income of \$1,000 to the seller. A similar assumption, of course, would have to be made for every subsequent round of spending.)

It is true that insofar as business sales revenues rise from year to year, on the foundation of a growing quantity of money and rising volume of spending, the greater portion of the additional sales revenues and accompanying profit incomes is spent by business firms in paying wages and in buying capital goods. But this is a *productive* expenditure, not a consumption expenditure. It is made out of the portion of the additional sales revenues and profits which are *not* consumed, but which are *saved*—something which, as I have said, the Keynesian analysis calls a “leakage,” and regards as unfortunate.

If the economic world operated in accordance with the ideals of Keynesian economics, and the greater part or all of the additional business sales revenues and profits were consumed, it would be disastrous for wage earners and for all business firms that sell to other business firms,

and even for those business firms that sell to consumers and which would have higher profit incomes. For the wage share of the national income would fall, the ratio of the value of capital to the value of output, (*viz.*, the degree of capital intensiveness) would fall, and the relative production of capital goods would fall. In short order, economic progress would be brought to a halt and economic retrogression would commence, as capital began to be decumulated. Both real wages and real profits would steadily decline.³¹ The interests of everyone in the economic system, but foremost the interests of wage earners, lie with the highest possible *productive* expenditure, which means: the lowest possible consumption expenditure on the part of those making productive expenditure.

Saving Versus Hoarding

Saving is the use of revenue or income by a business or individual for purposes other than expenditure on consumers' goods (or consumers' services). It is revenue or income that is not consumed.

Because what is saved is not spent by the saver for consumption, a popular fallacy has grown up that saving is synonymous with *hoarding*—i.e., with the retention of money in the manner of a miser. This fallacy is not so difficult to understand when committed by people with limited education, who thus know little beyond their own personal experience. Most such people are wage earners, who normally do not personally make any kind of expenditures but consumption expenditures. In the absence of wider knowledge, it is easy for such people to confuse consumption spending with all of spending and thus to conclude that what is not spent for consumption is simply not spent. But the fallacy is also prevalent in the press, which persists in equating an increase in the rate of saving with a decrease in the spending for goods. For example, whenever it is reported that some increase in the rate of saving has taken place, the press concludes that the effect must be economically dampening at the very least.

Worse still, the fallacy that saving is hoarding is prevalent among professional economists—notably the Keynesians and neo-Keynesians—who routinely describe saving as a “leakage” from the “spending stream.”³² (Such economists have taught the fallacy to the members of the press.)

Indeed, so complete has been the intellectual severance of saving from spending that for several decades it has been routinely taught in college and university classrooms not only that what is saved simply disappears from spending and depresses the economy, but also that what is invested virtually comes out of nowhere and financially stimulates the economy.³³ This is a state of confu-

sion that would be comparable to believing that the seeds a farmer scatters simply disappear, and that the crop that later comes up, comes out of nowhere. Yet such a state of confusion is the corollary of believing that saving is hoarding. If one recognized that investment comes from saving, one would have to recognize no less that saving goes into investment—that the two are merely different aspects of the same phenomenon. In that case, one would not view saving as depressing, nor investment as stimulating.

It must be pointed out that exactly the same kind of intellectual severance of cause and effect prevails in the belief that government spending represents an increase in total spending, while taxes represent a decrease in total spending. It is not seen that the taxes do not disappear from spending, but go to finance government spending, and that the government spending does not come out of nowhere, but, for the most part, out of taxes.³⁴ The objection to taxes is not that they reduce spending but that they transfer the power to spend from those who have earned it, and to whom it belongs, to those who have not earned it, and to whom it does not belong, and in the process reduce the total of what is produced.

It is not possible to emphasize too strongly that saving is not hoarding, for few fallacies are more destructive. Thus, before proceeding to show the actual positive contribution of saving to spending, which is enormous, it is necessary to show some of the fallacies that are present in the belief that there is any real or significant connection between saving and hoarding.

i. The Hoarding Doctrine as an Instance of the Fallacy of Composition

It should be realized that while any particular individual might save in the form of adding to his cash holding—that is, in the form of “hoarding”—it is not possible for the economic system as a whole to do so. Indeed, the belief that the economic system as a whole can save by means of hoarding is an instance of the fallacy of composition—the same fallacy encountered in connection with the belief that not only an individual industry or group of industries can overproduce, but that the economic system as a whole can overproduce.³⁵

The reason that an individual can save by means of hoarding cash, while the economic system as a whole cannot, is because whatever cash an individual adds to his holding, some other individual has had to subtract from his holding. If I sell my goods for \$1,000, say, and decide to retain that sum in the form of cash, it is true that I increase my savings in the form of cash by \$1,000. But in the very same period of time, the individuals to whom I have sold my goods have had to reduce their cash holdings, and thus their accumulated savings in the form

of cash, by that very same \$1,000. I have \$1,000 more in cash and in savings, but they have \$1,000 less in cash and in savings. Adding up the change not only in my position, but in theirs as well, it thus turns out that in the economic system as a whole there is no increase whatever in savings in the form of cash holdings. What some individuals save by means of adding to their cash holdings other individuals have had to dissave.

The situation of students in a classroom provides an excellent illustration of this proposition. At any given time, the members of the class have just so much cash in their possession. If the doors to that classroom were locked and that class became a “closed economic system” for an hour or so, with its members carrying on some form of production and buying and selling from one another, any individual student might increase his savings by adding to his cash holding over that interval of time. But then the rest of the class must decrease its savings in the form of cash holdings to exactly the same extent. There is no way that the class as a whole can increase its savings by increasing its holding of cash.

It follows that if there is to be saving in the economic system as a whole—that is, an increase in the savings of some or all members of the economic system that is not compensated for by a decrease in the savings of other members of the economic system—the only way it can take place is in the form of *an increase in assets other than cash*. The increase in the savings of the economic system as a whole must take the form of an increase in its capital assets, such as business plant, equipment, and inventories, or in its consumer assets, such as owner-occupied houses, personal automobiles, and home appliances. In this way, some or all members of the economic system can have an increase in their accumulated savings with no one having to have a decrease. (Consumer assets represent accumulated wealth and thus savings insofar as they retain their usefulness and a corresponding portion of their exchange value. They are consumers’ goods in that they are in the process of being consumed, but they represent wealth and savings insofar as they are not yet totally consumed. Furthermore, the purchase of such consumer assets is frequently made possible by means of borrowed funds, which from the point of view of the lender are capital, inasmuch as they are the source both of their own replacement and of income as well.³⁶)

The only exception to the principle that the economic system cannot save by means of adding to its cash holdings exists insofar as there is an increase in the quantity of money. If, over a period of time, the quantity of money in the economic system increases, then, to that extent, there can be an increase in the holding of cash that does not imply an equivalent decrease in the holding of cash by others. But this is the only exception, and it is of

absolutely no negative significance. Moreover, it is incapable inasmuch as the new and additional money must be added to the cash holdings of someone and in that capacity will constitute part of their savings.

ii. Hoarding as the Cause of a Reduction in Savings

Even though it is impossible that everyone could succeed in increasing his savings in the form of cash holdings (except to the extent that the quantity of money increased), it is possible that many people or even everyone might attempt to do so, in an effort to become financially more liquid. The effect of such an attempt is actually to *decrease the aggregate amount of accumulated savings stated in terms of money*. This is because the effect of such action is to reduce the monetary value of land and buildings, equipment and inventories, and, of course, stocks and bonds, which are claims against such assets. For all of these things are put up for sale in unusually large quantities, in the general effort to raise cash. At the same time, of course, the expenditures to purchase such assets are sharply curtailed, in efforts to retain cash. The fall in the aggregate monetary value of these items is what causes the fall in the total of accumulated savings stated in money. The reduction in such asset values on the left-hand side of the balance sheets causes a reduction in earned surplus and retained earnings accounts on the right-hand side of balance sheets, which accounts represent accumulated savings. Thus, it should be apparent that hoarding is not only not the same thing as saving, but actually operates to *reduce* the total of what has been saved.

This discussion indicates the true nature of hoarding when it occurs on a significant scale. It has nothing to do with any attempt to save or to save more; nor does it originate with consumers. Rather, it represents the attempt of business firms and investors to convert previously accumulated savings from their usual form of physical assets or claims to physical assets, into cash, in an effort to become more liquid. The attempt takes the form both of the outright sale of existing assets and the reduction of expenditures required for their replacement. And, in the process, as just explained, it reduces accumulated savings, along with consumption and all other forms of spending, and along with all forms of monetary revenue and income.

It should be realized that in such a process, what is saved out of current income easily becomes a *negative* number. That is, not only is saving out of current income reduced, not only is it wiped out altogether, but, in such circumstances, consumption actually comes to exceed current income. (This was the case, for example, in the Great Depression of the 1930s.³⁷) In part, this is because the contraction in spending that results from the desire to

become more liquid initially causes large-scale unemployment. To the extent that the unemployed have savings, they live off their savings. Even more important in terms of the size of the effect on savings, the decline in spending in the economic system reduces business sales revenues and profits. Yet even with sharply reduced profits or even outright losses, many businesses continue to pay dividends. Losses, and dividend payments in excess of profits, constitute a reduction in the accumulated savings of business enterprises. And on top of all of this is the capital losses previously referred to, which take place in connection with the sale of assets at prices below their cost of acquisition.

iii. In Defense of "Hoarding"

The fact that "hoarding," or, more correctly, the desire to increase cash holdings, operates to reduce saving no less than consumption, does not mean that it is an evil or should be prevented in any way. What the attempt to hold more cash does succeed in doing is *to increase the buying power of the stock of money*, whatever the stock of money may be. (This, of course, is if the attempt to hold more cash is not frustrated by laws interfering with the fall in wages and prices, and by fractional reserve banking in connection with checking deposits, which results in bank failures reducing the quantity of money.³⁸) By virtue of driving down the prices of other assets, of goods in general, and wage rates, it operates to make any given quantity of money stand in a higher ratio to the value of other assets and to spending for goods and labor. It thus operates to increase the degree of liquidity in the economic system and finally to put an end to the desire further to increase cash holdings. To say the same thing in somewhat different words, it operates to increase the so-called quick ratios of corporations and all other businesses and to place them and everyone else in a financially stronger position, in which their cash reserves stand in a higher ratio to their current liabilities, and in which, therefore, the general state of financial solvency is better assured. (Current liabilities are reduced because the fall in wages and prices means that the sums of money owing for any given physical volume of purchases by businesses are correspondingly less.)

If, once and for all, the economic system could achieve a sufficiently high degree of liquidity, and, as a major aspect of this, the threat of mass insolvencies were thereafter removed, there would be no further basis for any contraction in spending. The economic system would operate with less spending relative to the quantity of money (i.e., the so-called velocity of circulation of money would be lower), but that lower relative level of spending would no longer be subject to reduction. From that point on, spending in the economic system could

grow modestly from year to year, in line with a modest rate of increase in the quantity of money.³⁹

To achieve this highly desirable state of affairs, and, by the same token, to avoid periods in which the economic system is first led into a state of illiquidity through artificial stimulus to overspending, and is thus put in the position in which it requires a financial contraction to restore a sufficient degree of liquidity, what is necessary is a 100-percent-reserve gold standard. This will be shown in Chapter 19, which is devoted to the subject of inflation.⁴⁰

Saving as the Source of Most Spending

Apart from the case of occasional misers, revenue and income that is saved is not only spent fully as much as revenue and income that is consumed, but, in the conditions of a modern economic system, is always spent *on a far greater scale* than revenue and income that is consumed. This is because saving is the source of the demand for all of the labor employed by business firms and for all of the capital goods they buy, such as factory and office buildings, machinery and materials, components and supplies, and goods at wholesale. In addition, it is the source of the demand for all expensive consumers' goods.⁴¹ Even when it is necessary for business firms to reduce their expenditures for the replacement of assets, in order to build up liquidity, saving—on a gross basis, that is, out of business sales revenues—continues to be the source of far more demand than does consumption.

Nevertheless, the role of saving in spending is almost entirely unappreciated. It is unappreciated even in connection with the purchase of expensive consumers' goods, despite the fact that the savings of the ordinary wage earner and of many businessmen and capitalists are normally lent to borrowers precisely for the purpose of making possible the purchase of expensive consumers' goods, notably houses and automobiles. Thus let me begin by pointing out just how dependent is the purchase of expensive consumers' goods on the existence of savings.

Virtually no one can buy a house out of current income. Very few people can buy an automobile out of current income. Most people cannot buy any kind of major appliance or any other expensive consumers' good out of current income. To buy any good whose price exceeds the income of the current pay period, or constitutes any substantial portion of the income of the current pay period, which for most people is only a week or two, it is absolutely indispensable that the buyer have access to savings—either his own or those of a lender. There simply is no other way. If a good costs the income of three years, as is typically the case with houses, then there is no conceivable way that it can be bought without savings. Indeed, if a good costs the income of three weeks, its purchase will require savings. If it costs even as much

as a third of the income of one week, it will probably require savings if its purchase is to be possible, for it probably could not be afforded if it had to deprive the buyer of so much of his other consumption for the week. Saving exists any time income of one pay period is carried over for expenditure on consumers' goods in a later pay period.

In view of these facts, it is nothing short of amazing that serious economists and the financial press could believe that saving depresses spending. Saving is absolutely essential to the spending for housing, automobiles, appliances, and every other expensive or even moderately expensive consumers' good. But these facts only barely begin to indicate the role of saving in spending.

The far greater part of the *wages* paid in the economic system are paid out of savings. In many cases—especially in manufacturing, mining, construction, and agriculture—the period of time which elapses between a wage earner's performance of labor and the readiness for sale of the product he helps to produce exceeds the period of time between the wage earner's performance of labor and the payment of his wages by the employer. For example, a wage earner is typically paid after the performance of one or two week's work. But the product he helps to produce is often not completed and ready for sale for a much longer period than that. In many cases months, and sometimes several years, go by after the completion of a given worker's work and the readiness of his product for sale. In such cases, the worker's wages are paid out of the employer's capital.

Even in those cases in which the wage earner's work contributes to the production of a product that can be sold before it is necessary for the employer to pay his wages, it is probable that the employer will not be *paid* for the product until after he has paid the wages in question. Typically, this is the case whenever the employer sells the product on any kind of credit terms, such as the common practice of giving the customer thirty days in which to pay his bill. In cases of this kind, the source of wages is again clearly the employer's capital, which, of course, represents accumulated savings.

Finally, even in those instances in which the wage earner's work contributes to the production of a product or service for which the employer is paid by the customer *prior* to the payment of the wage earner's wages—such as the case of a waiter or waitress in a restaurant whose customers usually pay in cash rather than by means of credit cards—the payment of the wages still rests on an act of saving, in that the wages are paid with revenues that belong to the employer and which he does not consume. The employer's payment of wages in such cases is still a productive expenditure, not a consumption expenditure. And to make it, the employer must not

consume, but save the sales revenues in question.

The only wages in the economic system that are not paid out of savings and which are in fact paid by consumers are wages paid *not for the purpose of making subsequent sales*, i.e., wages paid not for business purposes. The leading examples are the wages of domestic servants and the wages of government officials. And even though the government's payroll is certainly grossly excessive, the proportion of total wage payments in the economic system as a whole that is constituted by consumption expenditure is relatively modest notwithstanding. This is indicated by the fact that while in the United States there are some 18.6 million government employees, whose wages represent consumption expenditure, there are over 90 million employees of private business firms, whose wages represent productive expenditure.⁴²

Not only are most wages paid out of savings and constitute productive expenditure, rather than consumption expenditure, but, as I have indicated, the same thing is true of the purchase of *goods* as well. All the goods which businesses purchase at wholesale are paid for out of savings, and the funds expended constitute productive expenditure. All of the machinery, equipment, furnishings, fixtures, factories, and office buildings that businesses buy or pay to have constructed, all of the purchases of materials, components, parts, supplies, fuel, lighting and heating, and so forth that businesses make are paid for out of savings and constitute productive expenditure.

When such purchases—which, of course, must be described as purchases of capital goods—are added up, it is virtually certain that they substantially exceed the purchases of consumers' goods. For example, the sum of the purchase of groceries at wholesale by supermarkets and grocery stores, plus the expenditure for food products by the wholesalers, plus the expenditure for the various ingredients and other supplies by the food processors or manufacturers (which almost always take place at more than one stage of production), plus the expenditure for such things as feed and fertilizer by the farmers, plus the expenditure by all the parties involved for machinery, equipment, fixtures, buildings, power and light, and the like, plus the further expenditures for capital goods by the makers of these things—all these expenditures for capital goods taken together almost certainly add up to substantially more than the expenditure for groceries by consumers at the one, final stage that is constituted by retailing.

Essentially the same principle applies to the cases of clothing, housing, and transportation, and to the economic system in general. Thus, the expenditure to buy capital goods almost certainly exceeds the expenditure to buy consumers' goods. (It necessarily must do so if the percentage of sales revenues of the average business that

corresponds to its costs on account of capital goods, including services purchased from other business firms, is anything greater than 50 percent. If, for example, it were 60 percent, then taking the demand for consumers' goods as 100, the demand for capital goods would be expressible as equal to the sum of $.6 \times 100 + .6^2 \times 100 + .6^3 \times 100 \dots + .6^n \times 100$, which ultimately equals 150.)

Even if the expenditure to buy capital goods by itself did not exceed the expenditure to buy consumers' goods, it would still be the case that total productive expenditure, which includes both the demand for capital goods and the demand for labor by business together, far exceeds consumption expenditure. For example, in the case of supermarkets, where the average profit margin is only 2 percent or less, the implication is that 98¢ of every dollar of sales is productively expended (which is why costs come to equal 98 percent of sales revenues). If, of these 98¢ of productive expenditure by the supermarkets, 60¢ are for capital goods whose sellers earn, say, a 10 percent profit margin and productively expend 90 percent of their sales receipts, then, already, productive expenditure equals \$1.52 for every \$1 of sales receipts from consumers—that is, it equals 98¢ plus 54¢. Of course, it will equal substantially more when the productive expenditures of still more remote stages are added in. Such a relationship between productive expenditure and consumption expenditure prevails throughout the economic system.

It should be realized that not only do saving and productive expenditure far exceed consumption expenditure, but also that they are the *source* of almost all consumption expenditure. The wages paid by business enterprises are the source of most consumption expenditure in the economic system, in that they provide the great majority of people with the incomes out of which they consume. They are also the source of all that consumption expenditure of the government and its employees which is financed with taxes paid out of the wages of the employees of business enterprises.

For the rest, business—in the productive process—is the source of almost all other consumption. What it does not provide for consumption in the way of wage payments, it provides in the way of dividend and interest payments and in the taxes that it itself pays. The only consumption expenditure of which business is not the source is consumption out of newly created fiat money.

From the perspective of the economic system as a whole, *consumption depends on saving and the productive process*—not only in physical terms, but in terms of the financial process of paying out and taking in money. As subsequent discussion in this section and throughout this book will confirm, from the perspective of the economic system as a whole, it is the consumers who are

dependent on business, not business on the consumers. The well-known dependence of business on the consumers, which the Austrian school has done so much to demonstrate, and which I myself have elaborated upon in previous chapters, exists at the level of the individual firm and industry, where competition prevails. But at the level of the economic system as a whole, the competition of the individual firms and industries is mutually offsetting, and there the consumers are dependent on business.

The “Macroeconomic” Dependence of the Consumers on Business

As I have said, from the point of view of the economic system as a whole, it is the consumers who are dependent on business, not business on the consumers. Any individual business, any individual industry, to be sure, is always vitally dependent on its customers, and, in the last analysis, on the customers for the final products—the consumers’ goods—it directly or indirectly helps to produce. But this is because of the existence of competition among the different business firms and the various industries. The consumers have the power to choose *which* individual business firms and individual industries will receive back the funds they have provided the consumers with—which will receive back more and which will receive back less. But it is nothing but the fallacy of composition to generalize from this “microeconomic” dependence of the individual business and industry on the consumers to a “macroeconomic” dependence of business as a whole on the consumers. When the entire business system is viewed at once, the consumers have no alternative but to spend. Their desire to live and enjoy life impels them to spend. And, of course, their savings, made as provision for the future, are also spent—by virtue of being spent for business purposes, by virtue of being lent to borrowers who spend them either for business purposes or for consumption, and, to some degree, by virtue of being spent for consumption by the savers themselves, later on.

Thus, at the level of the economy as a whole, the dependency is not that of business on the consumers, but, as I say, of the consumers on business. As we shall see, business is in no way dependent on the existence of any definite minimum demand for consumers’ goods, for the demand for capital goods is as much a demand for the products of business as is the demand for consumers’ goods.⁴³ At the same time, the consumers are vitally dependent on business for their physical means of survival, well being, and enjoyment. As a result, whatever cash they possess is pulled toward business with the force of a magnet, as it were. At most, it is only a question of how soon they will be drained of all the cash they possess, unless they find ways of continually replenishing their cash by obtaining fresh funds from business, in

exchange for the sale of their labor or in the form of dividends or interest paid by business. The phrase “circular flow of income and expenditure,” so popular in today’s macroeconomics textbooks, with its implied equality of dependence of consumers on business and business on consumers, is inaccurate. The fact is that *money comes to goods*—automatically, on the strength of people’s desire to live and enjoy themselves. What is not automatic, but requires the continuous exercise of intelligence, will, and effort is the process of production.

Consequently, the consumers are dependent on business not only for the production of the products they buy, and thus for the purchasing power of the money they spend in buying them, as I showed in Chapter 13, but also for *the monetary means* of buying them. Apart from the creation of fiat money (which is always a process that tends to undermine production and thus, in the long run, the ability to consume), it is only the expenditures and disbursements of business enterprises that place money in the hands of consumers; only to the degree that one contributes to the production of products to be sold or receives money from those who do, can one obtain the monetary means of consumption.

i. Business as the Source of Its Own Demand and Profitability

Consistent with the preceding, business does not need any outside class of consumers—any deliberately created class of consumers. *It itself generates a monetary demand that is fully sufficient for the profitable sale of its products.* It does so in the mere fact of purchasing capital goods and paying wages and in declaring dividends and paying interest. In addition, the very increase in production itself operates to add further to both the real and the nominal rate of profit (the latter insofar as part of the increase in production is an increase in the supply of precious metals, with the result that under a system of commodity money the by-product of the increase in production is an increase in the quantity of money). I will show all of this in the next chapter, which sets forth my theory of profit and interest, namely, the net-consumption/net-investment theory.

The existence of depressions does not contradict the truth of any of these propositions. The wiping out of profitability that accompanies a depression is the result of a reduction in productive expenditure, which reduces the demand for capital goods, wage payments, and the consumption expenditure of wage earners. Profits are slashed because while these developments reduce the sales revenues of business, its aggregate costs continue to reflect the higher levels of productive expenditure prevailing in the past.

The reduction in productive expenditure, in turn, is

the result of a need of business firms to rebuild their cash balances relative to their outlays and revenues, which need arises because a preceding inflation and credit expansion first induced them to run down their cash balances relative to their outlays and revenues, and to incur unduly large debts besides. The problem of the decline in productive expenditure and sales revenues is compounded by the decline in the quantity of money that can occur under a system of fractional reserve banking.

The solution to the problem of monetary contraction and the wiping out of profitability it engenders is to establish a monetary system which prevents undue increases in the quantity of money, and which prevents decreases in the quantity of money. In preventing the undue increases in the quantity of money, the consequent unduly low level of demand for money for holding would also be prevented, and thus the resulting potential for sudden sharp increases in the demand for money for holding would be eliminated. (For example, in the absence of credit expansion, businessmen would not be misled into believing that they could substitute the prospect of obtaining loans easily and on profitable terms for the holding of actual cash balances. They would thus not be faced later on with the need suddenly to rebuild their cash holdings when the credit expansion was succeeded by a so-called credit crunch.) In these ways, the potential for depressions would be eliminated. Under such a monetary system, productive expenditure and sales revenues would show a modest increase from year to year, accompanying the increase in production and its by-product a modest increase in the quantity of commodity money. Corresponding to the increase in the quantity of commodity money, the nominal rate of profit would, as I say, be moderately elevated. Such a monetary system is, of course, a 100-percent-reserve gold standard.

But even without such a monetary system, business again and again recovers from the depressions inflicted upon it. Once wage rates adjust to the lower level of productive spending, and assets and indebtedness are written down, then, as the net-consumption/net-investment theory of profit will show, virtual "*springs*" to the restoration of profitability come into play, which act as a guarantee of recovery.⁴⁴

ii. No Need for Artificial Consumption

The corollary of the fact that business is the source of its own monetary demand and profitability is that consumers have absolutely nothing of value to offer business that is apart from their contribution to the productive process. The money they spend in buying from business is of value to business only insofar as they have first received it from business, in connection with such contribution. In the case of the consumption of wage earners,

business first receives services equivalent in monetary value to the means of consumption which it places in their hands. In the case of the owners and creditors of business enterprises, consumption is a matter of those whose activity underlies and guides the whole productive process consuming a portion of their own property. If it were financed on a voluntary basis, no criticism could be made even of the government's consumption insofar as it was for the purpose of carrying out its strictly limited and indispensable functions, which are an essential safeguard of the productive process.⁴⁵

But it is an altogether different matter when consumption takes place allegedly in order to benefit business by the very fact of its being consumption. Such consumption, which invariably takes place in the form of unnecessarily large government spending, whether financed by additional taxation or by an expansion of the money supply, can only be detrimental to business. If the government imposes additional taxes on business to finance its additional expenditures, then what it does is first reduce the cash holdings of business, and then restore them in the purchase of its products. The effect is that the government consumes without giving business anything in return. Indeed, to produce for the government's consumption, business is correspondingly prevented from producing capital goods for its own use or consumers' goods for the consumption of its employees and owners and creditors. The taxes it pays deprive it of the ability to purchase capital goods and to pay wages, dividends, and interest. The taxes thereby reduce the demand for capital goods and for consumers' goods by wage earners and dividend and interest recipients. Thus, the government's demand takes the place of these demands.

If the taxes are imposed directly on wage earners, then the government's consumption is mainly substituted for their consumption, and the loss falls mainly on them, with the likely outcome that their motivation to work is reduced.

If the taxes are imposed directly on dividend or interest recipients, the effect is largely the same as if they were imposed on business enterprises themselves, for it is to reduce the demand for capital goods and labor. Indeed, this is the overwhelming effect in both cases—that of business enterprises themselves and dividend and interest recipients—inasmuch as the consumption of businessmen and capitalists is governed mainly by the size of their capitals rather than their after-tax incomes, and will thus be reduced relatively little by the taxes, which means that the taxes will fall mainly on saving and productive expenditure.⁴⁶

If the government finances its additional expenditures by means of an expansion of the money supply, then in return for what it consumes, it gives money. But the

additional money is of no benefit to the economic system, for either in the very spending of it prices are correspondingly increased or prevented from falling, with the result that the government's added purchases come at the expense of the reduced purchases of the citizens, or inventories are drawn down, thereby leaving business with more money but a smaller supply of assets with which to carry on production. In addition, all the other destructive effects of inflation ensue.⁴⁷

In closing this discussion of artificially created consumption, it is appropriate to quote the words of John Stuart Mill on the subject:

It is not necessary, in the present state of the science, to contest this doctrine in the most flagrantly absurd of its forms or of its applications. The utility of a large government expenditure, for the purpose of encouraging industry, is no longer maintained. Taxes are not now esteemed to be "like the dews of heaven, which return again in prolific showers." It is no longer supposed that you benefit the producer by taking his money, provided you give it to him again in exchange for his goods. There is nothing which impresses a person of reflection with a stronger sense of the shallowness of the political reasonings of the last two centuries [the seventeenth and eighteenth], than the general reception so long given to a doctrine which, if it proves anything, proves that the more you take from the pockets of the people to spend on your own pleasures, the richer they grow; that the man who steals money out of a shop, provided he expends it all again at the same shop, is a benefactor to the tradesman whom he robs, and that the same operation repeated sufficiently often, would make the tradesman's fortune.

In opposition to these palpable absurdities, it was triumphantly established by political economists, that consumption never needs encouragement. All which is produced is already consumed, either for the purpose of reproduction or of enjoyment. The person who saves his income is no less a consumer than he who spends it: he consumes it in a different way; it supplies food and clothing to be consumed, tools and materials to be used, by productive labourers. Consumption, therefore, already takes place to the greatest extent which the amount of production admits of; but, of the two kinds of consumption, reproductive and unproductive, the former alone adds to the national wealth, the latter impairs it. What is consumed for mere enjoyment, is gone; what is consumed for reproduction, leaves commodities of equal value, commonly with the addition of a profit. The usual effect of the attempts of government to encourage consumption, is merely to prevent saving; that is, to promote unproductive consumption at the expense of reproductive, and diminish the national wealth by the very means which were intended to increase it.⁴⁸

Saving as the Source of Increasing Aggregate Demand, Both Real and Monetary

Saving is not only the source of most spending at any given time, but it is also a vital source of the increase in

aggregate real demand. Our discussion of Say's Law has shown that aggregate real demand is determined by aggregate supply.⁴⁹ We have also seen that saving vitally contributes to the increase in aggregate supply by bringing about the dedication of a sufficiently high proportion of existing factors of production to the production of capital goods, which, in turn, makes possible capital accumulation, a rising productivity of labor, and thus an increasing supply of goods coming to market. We saw too that it contributes to the same result insofar as it raises the degree of capital intensiveness in the economic system and thereby permits the implementation of a wider range of technological advances. Thus, saving operates to increase aggregate real demand.⁵⁰

Previous discussion has also shown that there is no fundamental scarcity of any natural resource, including the precious metals, and thus that general increases in the ability to produce are bound to result in an increase in the supply of the precious metals.⁵¹ It follows that under a system of commodity money the effect of saving—if carried on, on a sufficient scale—is, indirectly, to bring about an increase in the quantity of money. This, of course, is the foundation for a rising aggregate monetary demand—a rising volume of total spending in the economic system—over time. Thus, saving not only does not reduce the total of what is spent in the economic system, but, under commodity money, operates positively and progressively to increase it!

As illustration of this principle, one can take the whole of economic history since the beginning of the Industrial Revolution. The massive capital accumulation and rising productivity of labor of the modern era would have been impossible without the very great increase in the degree of saving and capital intensiveness that took place in comparison with previous eras. A virtually inevitable concomitant of the process, reflecting improvements that thereby became possible in mining, transportation, and engineering, metallurgical, and chemical processes in general was a much more rapid rate of increase in the supply of the precious metals than had previously occurred. Because of its high degree of saving and capital intensiveness, the modern era surpasses previous eras in its ability to increase the supply of precious metals as well as in its ability to increase the supply of goods in general.

Saving as the Source of Rising Consumption

It further follows from the preceding discussions that saving is the source of an increase in consumption, both in real and in monetary terms.

Insofar as more saving means more production of capital goods at the expense of less production of consumers' goods, the drop in consumers' goods production

is strictly temporary. Once the additional supply of capital goods comes into existence, it increases the total ability to produce in the economic system. The result is that the supply of consumers' goods begins to come back up and the supply of capital goods is further increased. The further increase in the supply of capital goods makes possible a further increase in the supply both of consumers' goods and capital goods. Soon the production of consumers' goods surpasses the level it held prior to the shift of factors of production to the production of capital goods, and with each passing year it does so by an ever widening margin.⁵²

To employ the popular economic analogy of shares of a pie, the smaller is the proportion of the economic pie that is devoted to the production of consumers' goods and the larger the proportion that is devoted to the production of capital goods, the more rapidly does the total pie grow. The result is that soon, in absolute terms, the smaller consumption share of a growing, or more rapidly growing, economic pie surpasses the larger consumption share of the concomitantly fixed, or less rapidly growing, economic pie.

As an illustration of this principle, one need only consider the post-World War II economic history of Japan. Japan has achieved rapid economic progress in large part by means of devoting a greater proportion of each year's production to the production of capital goods than almost any other country. The result has been that each year the Japanese economy is able to take advantage of a substantially larger supply of capital goods than the year before and to produce a correspondingly larger output. The larger output is the source both of more consumers' goods and more capital goods. Because of its low relative production of consumers' goods and high relative production of capital goods, Japan is today able to consume vastly more in absolute terms than would have been possible otherwise.

What is true in real terms is no less true in monetary terms. The growing quantity of precious metal money that general increases in the ability to produce make possible soon increase the total ability to spend to the point that the smaller proportion of total spending that is constituted by expenditure for consumers' goods comes to surpass in absolute terms the larger proportion previously devoted to expenditure for consumers' goods. This phenomenon, of course, is reinforced by the fact that countries whose economies grow relative to the world average attract a growing proportion of the world's money supply.⁵³ In today's monetary conditions, Japan's rapidly growing increase in ability to produce is responsible for the fact that consumption expenditure in the Japanese paper currency now represents enormously more than it used to, both in real terms and as a fraction of total

consumption expenditure in the world economy.

As a final point in connection with the relationship between consumption and saving, it should be explicitly understood that insofar as what is saved is used to pay wages, there is little or no drop in consumption spending even temporarily. For the wage earners use the far greater part of their wages to consume. Closely related to this point is the fact that most saving by wage earners is used to finance the purchase of expensive consumers' goods, such as houses or automobiles, or at least has its counterpart in the use of savings for this purpose. To this extent, as I say, saving does not represent a drop in consumption spending even temporarily. Of course, to this extent, saving also does not operate to bring about any progressive increase in production and the quantity of money, either. These results occur only insofar as saving brings about an increase in the relative production of capital goods and decrease in the relative production of consumers' goods. This occurs primarily, as we shall see, to the extent that businessmen and capitalists reduce the proportion of their sales revenues that they consume and increase the proportion that they save and productively expend.

3. Aggregate Economic Accounting on an Aristotelian Base

The purpose of this section is to reconcile national income accounting with the Aristotelian proposition that the demand for A is the demand for A , and with the consequent further proposition that most spending in the economic system is productive expenditure, not consumption expenditure. This is essential in that contemporary national income accounting gives every appearance of supporting the opposite and totally wrong conclusions that consumption spending, besides purchasing consumers' goods, pays most of the incomes in the economic system and is far and away the main form of spending. This section will demonstrate that when properly understood, national income accounting fully confirms the propositions I have advanced.

The central accounting relationship recognized by contemporary economics is that national income—consisting of the sum of all profit, interest, wage, and rental incomes—equals the sum of consumption spending plus net investment, which last sum is called the net national product (NNP). Symbolically,

$$p + w + i + r = Y = NNP = C + I,$$

where p = profits, w = wages, i = interest income, r = rental income, Y = national income, C = total consumption spending, and I = net investment.

According to contemporary economics, when depreciation allowances are added to the aggregate profit component of national income, profits are raised to gross profits and national income is raised to gross national income. When the same depreciation allowances are added to net investment, net investment is raised to “gross” investment, consisting of spending for plant and equipment plus, be it noted, the *net* change in business inventories. At the same time, NNP is raised to GNP.⁵⁴

The reason that the addition of depreciation allowances to net investment has the above result follows from the nature of net investment. Net investment is the sum of net investment in plant and equipment plus net investment in inventories. Net investment in plant and equipment is equal to expenditure to purchase plant and equipment minus depreciation allowances. Thus, when depreciation allowances are added back in, net investment in plant and equipment is raised to gross investment in plant and equipment, i.e., to expenditure for plant and equipment. However, it is a curious and highly misleading use of terms to call the sum of gross investment in plant and equipment plus the *net* investment in inventories “gross investment.” It is part and parcel of the misidentification of gross national product as the final product, which, of course, is nothing more than the *net* national product. In other words, it is an instance of the pervasive confusion on the part of contemporary economics between gross and net. As I will show, a true gross investment figure would require the further addition of *cost of goods sold*, which would raise net investment in inventories to productive expenditure on account of inventory.⁵⁵ As matters stand, gross national product is explicitly presented as the sum of consumption expenditure plus a gross investment that is actually net investment as far as inventories are concerned.

The Consumption Illusion of Contemporary National-Income Accounting

The misconceptions of contemporary economics concerning the nature of what is produced and what is purchased both profoundly influence and, in turn, are greatly reinforced by contemporary national income accounting. The equality between national income, on the one side, and consumption plus net investment, i.e., net national product, on the other, is interpreted to mean that consumption and net investment *pay* the national income. And because consumption spending is several times larger than net or even gross investment, contemporary economics assumes that consumption spending pays the far greater part of national income and constitutes the far greater part of spending for goods and services in the economic system. This view is present in every depiction of national income as being determined

Figure 15–2
The “Keynesian Cross”

by the sum of consumption plus net investment. It is blatantly obvious in the so-called Keynesian-cross diagram of Figure 15–2, which is an integral part of every contemporary macroeconomics textbook and is faithfully reproduced there.⁵⁶

According to this diagram, consumption pays an amount of income equal to E , if net investment does not exist at all. Given the existence of net investment, which is depicted as the vertical distance between the C and the $C + I$ lines, consumption is held to pay an amount of income equal to E' minus I . By following the dashed lines down from E' to the $C + I$ line and then across to the vertical axis, one can see that this amount of consumption is supposedly equal to C' .

As we have seen, of course, the actual fact is that most spending and income payments are constituted by productive expenditure, not consumption expenditure. The equality between national income, on the one side, and consumption plus net investment, on the other, represents an optical illusion, as it were, insofar as it leads to the conclusion that consumption is the major item of spending and pays most of the incomes in the economic system. Actually, most of the spending and income payments in the economic system are *concealed under net investment*, which, in effect, is the visible portion of an iceberg. For net investment, as we shall see, is *the difference between total productive expenditure in the economic system and aggregate business costs*—that is, the aggregate of the costs that business firms deduct from

their sales revenues in calculating their profits.

All this becomes obvious if we take the trouble to go through a step-by-step derivation of the equality of national income with consumption plus net investment. I begin with a simplified definition of national income as the sum of profits plus wages. (I count interest income and all genuine “net rental incomes of persons” under the heading of profits. I do so not only for the sake of simplicity, but also because of their actual economic nature.⁵⁷)

Thus, we have, by definition,

$$(1) \quad p + w = Y,$$

where p = profit, w = wages, and Y = national income.

We also have, by the common accounting definition of profit,

$$(2) \quad p = s - d,$$

where s = aggregate business sales revenues, and d = aggregate business costs deducted from sales revenues in calculating profits.

It follows that by substituting (2) into (1), we obtain

$$(3) \quad s - d + w = Y.$$

At this point I divide sales revenues and wage payments from the perspective of the purpose of the parties paying the sales revenues or wages, that is, from the perspective of whether the expenditures are made *for* the purpose of making subsequent sales or *not* for the purpose of making subsequent sales. My procedure is strictly in accordance with the concepts I developed earlier, in Chapter 11.⁵⁸ Thus, we now obtain

$$(4) \quad s = s_c + s_b$$

and

$$(5) \quad w = w_c + w_b,$$

where s_c = that part of total business sales revenues paid by consumers, i.e., paid not for the purpose of making subsequent sales; s_b = that part of total business sales revenues paid by business firms, i.e., paid for the purpose of making subsequent sales; w_c = that part of total wages paid by consumers, i.e., paid not for the purpose of making subsequent sales; and w_b = that part of total wages paid by business, i.e., paid for the purpose of making subsequent sales.⁵⁹

I must stress that s_c , s_b , w_c , and w_b represent *revenue-expenditure subcomponents* of national income and net national product in that they simultaneously represent revenue or income, when viewed from the perspective of sellers, and expenditure, when viewed from the perspective of buyers.

Now, by substituting equations (4) and (5) into equation (3), we obtain

$$(6) \quad s_c + s_b - d + w_c + w_b = Y.$$

The verbal meaning of equation (6) is that national income is equal to the sum of the part of business sales revenues constituted by consumption expenditure plus the part of business sales revenues constituted by productive expenditure, minus business costs, plus the sum of the part of wages constituted by consumption expenditure plus the part of wages constituted by productive expenditure—that is, that national income is still equal to the sum of profits plus wages, but expressed now in terms of their revenue-expenditure subcomponents.

It further follows that by a change in the order of addition of the revenue-expenditure subcomponents, we obtain

$$(7) \quad s_c + w_c + s_b + w_b - d = Y.$$

Now, one should realize that

$$(8) \quad s_c + w_c = C,$$

that is, that consumption expenditure for goods and services purchased from business firms plus consumption expenditure in payment of wages equals total consumption expenditure constituting revenue or income.

In addition, one should realize that

$$(9) \quad s_b + w_b = B,$$

that is, that productive expenditure for goods and services purchased from business firms plus productive expenditure in payment of wages equals total productive expenditure constituting revenue or income.

By substituting equations (8) and (9) into equation (7), it follows that

$$(10) \quad C + B - d = Y.$$

Essentially all that remains is to realize that

$$(11) \quad B - d = I,$$

for reasons to be explained shortly.

Thus, finally, by substituting equation (11) into equation (10), we see that

$$(12) \quad C + I = Y.$$

Consequently, we see that the equality between national income and net national product turns out to be a mathematical identity, in which the only difference is a change in the order of addition of identical terms, namely, the revenue-expenditure subcomponents and aggregate business costs.

The full statement of the relationship between national income and net national product is

$$(13) \quad Y = p + w = (s_c + s_b - d) + (w_c + w_b) = (s_c + w_c) + (s_b + w_b - d) = C + B - d = C + I = NNP.$$

The first formulation is national income in terms of its income components, profits and wages; the next formulation is national income in terms of its revenue-expen-

diture subcomponents; then, by a rearrangement of the order of addition, *net national product* in terms of its revenue-expenditure subcomponents; then net national product in terms of its expenditure components, namely, consumption expenditure plus productive expenditure minus business costs; and finally, net national product stated as the sum of consumption plus net investment.⁶⁰

*i. Net Investment as Productive Expenditure
Minus Business Costs*

I now must show why productive expenditure minus business costs—the same costs as are deducted from sales revenues in calculating profits—equals net investment. This, of course, is the demonstration of equation (11) above—namely, $B - d = I$.

For the benefit of readers with no background in business accounting, I offer as helpful adjuncts the essential elements both of a business balance sheet and of a business income statement. The balance sheet appears as Figure 15–3, and the income statement as Figure 15–4. In the balance sheet, our focus will be on the “Inventory and Work in Progress” account and on the three fixed-asset accounts “Gross Plant and Equipment and Other Fixed Assets,” “Accumulated Depreciation Reserve,” and “Net Plant and Equipment and Other Fixed Assets.” (For the sake of brevity, I will often refer just to plant and equipment, though it should be realized that everything that applies to their accounting treatment applies to the accounting treatment of other types of fixed assets as well, such as office buildings, warehouses, and pipelines.) In the income statement, our focus will be primarily on the two cost elements “Depreciation” and “Cost of Goods Sold.”

The reason that productive expenditure minus business costs equals net investment is that productive expenditure (viewed from the perspective of those making the productive expenditures) represents debits or pluses to the above asset accounts in the balance sheets of business firms, while business costs represent credits or minuses to those asset accounts. The difference between the sum of the pluses and the minuses is the *net change* in the asset values of business firms. This net change in the balance-sheet value—the so-called book value—of business assets is *net investment*.

Productive expenditure embraces the outlays for plant and equipment and all other fixed assets by business. It also embraces the outlays for materials, components, and supplies by business—viz., all the items entering into work in progress or inventories. These outlays represent both purchases of capital goods and wage payments. The outlays for machinery, materials and other capital goods can probably be readily understood as representing additions to asset accounts. But wage payments too are

included in the items debited to asset accounts. For example, the wages of construction workers come under the heading of productive expenditure on account of plant and equipment and are debited to the gross plant and equipment account. The wages of direct manufacturing labor come under the heading of productive expenditure on account of work in progress or inventories and are debited to the inventory and work in progress account.

These productive expenditures are related to the costs of production incurred by business firms, but they do not show up directly and immediately as costs of production. Instead, as I have just indicated, they are *capitalized*—that is, debited to the plant and equipment or inventory and work in progress accounts. Only later, as the plant and equipment or other fixed assets that have been purchased *depreciate*, and when the inventories that have been purchased or that result from work in progress are *sold*, do these productive expenditures show up as costs of production in business income statements, where they are deducted from sales revenues in arriving at profits. And at that time, the costs, in the form of depreciation and cost of goods sold, represent a *decapitalization* of assets—that is, they are deducted from the plant and equipment or inventory and work in progress accounts.

The relationships can be illustrated at the level of an individual company. Thus, for example, if a company spends \$10 million to construct a new factory, which will last 50 years, it certainly does not deduct that \$10 million from its current year’s sales revenues. Instead, the sum is capitalized, in the form of being added to its gross plant and equipment account. Depending on the particular depreciation method employed, the \$10 million acquisition cost of the factory may very well show up as an annual depreciation cost of \$200,000 for each of the next 50 years. And as the depreciation costs are incurred, the net value of the factory on the company’s books undergoes a corresponding diminution. While its acquisition value of \$10 million stays on the company’s books under the heading gross plant and equipment so long as the factory is owned, each passing year is accompanied by a \$200,000 increase in the accumulated depreciation reserve against the factory. Thus, each year the value shown for the factory under the heading net plant and equipment declines by \$200,000. If the firm had no other purchases of plant and equipment, it would show a net investment of \$10 million in the period in which the factory was being constructed, and thereafter a net *disinvestment* of \$200,000 a year. The principle is that the outlay is capitalized—added to assets—and the depreciation cost corresponding to the outlay represents decapitalization—a subtraction from assets.

Exactly the same principle applies to inventory and

Figure 15–3
The Elements of the Balance Sheet

ASSETS	LIABILITIES
Cash	Borrowed Capital
Gross Plant and Equipment and Other Fixed Assets	
less: Accumulated Depreciation Reserve	
Net Plant and Equipment and Other Fixed Assets	Equity Capital
Inventory and Work in Progress	

work in progress. For example, if an automobile company spends \$1 billion in November or December to produce automobiles that it will not sell until January or February of the following year, its outlay of \$1 billion does not show up in its costs deducted from sales revenues in the current year. Instead, the outlay is capitalized in its inventory or work in progress account, which is increased by that amount. Only next year, when the resulting automobiles are sold, will the \$1 billion show up as a cost deducted from sales revenues. It will show up under the heading “cost of goods sold.” And when the automobiles are sold, the inventory and work in progress account of the automobile company is decreased by \$1

billion. In other words, the \$1 billion of cost of goods sold in the company’s income statement will correspond to a disinvestment of a \$1 billion in its inventory and work in progress account.

Once again, the sequence is: productive expenditure, capitalization of productive expenditure in asset account, decapitalization of asset account, cost in income statement.

It should be obvious that to whatever extent any company makes productive expenditures for plant and equipment or other fixed assets that are greater than the depreciation cost it incurs in the same period of time, it experiences a corresponding increase in the value of its

Figure 15–4

Selling, General, and Administrative Expenses
Net Profit Before Taxes

plant and equipment account net of accumulated depreciation. For it has capitalized a larger sum under the heading of gross plant and equipment than it has decapitalized under the heading of accumulated depreciation reserve. To state the matter in slightly different words: The sum of all of a company's outlays past and present for the plant and equipment that is still in its possession is its gross plant and equipment account. When the total of accumulated depreciation on all of those assets is subtracted from the gross plant and equipment account, the result is the net plant and equipment account. To the extent that in any given year a company makes productive expenditures for plant and equipment in excess of that year's depreciation charges, it adds more to the value of its gross plant and equipment account than it adds to the accumulated depreciation reserve that is deducted from that account. Thus, the value of its net plant and equipment account increases to precisely the same extent. This increase in the value of the net plant and equipment account is, of course, net investment in plant and equipment.

In just the same way, to whatever extent any company makes productive expenditures on account of inventories or work in progress that exceed the cost of goods sold it incurs over the same period of time, it must have a corresponding net investment in inventory/work in progress. This is because its productive expenditures for inventory or work in progress will have added to this account a larger sum than its cost of goods sold has subtracted from it, and thus it will have an increase in the book value of its inventory/work in progress account.

It should be realized that implicit in the preceding discussion is the fact that net investment need not always be positive. It can be a negative number. This will be the case if current outlays for plant and equipment are less than current depreciation charges, or if current outlays for inventory or work in progress are less than cost of goods sold. Such conditions exist in the descent into a depression, when productive expenditure sharply declines, while costs, especially depreciation, fall to a much lesser extent, owing to their determination by productive expenditures of the past.

Now productive expenditures on account of plant and equipment and other fixed assets, and on account of inventory and work in progress, do not account for all of productive expenditure, nor do depreciation and cost of goods sold account for all of business costs. There are expenditures firms make in buying from other firms and in paying wages, which are *expensed*—that is, not debited to physical assets, but deducted as they are made, from sales receipts. Expenditures are expensed, as a rule, when they do not directly contribute to the buying firm's acquisition of tangible goods. This is the situation, for

example, with respect to the salaries of sales and clerical help, advertising outlays, and lighting and heating bills. Such expenditures can be taken as coinciding with the cost category "Selling, General, and Administrative Expenses" in the income statement of Figure 15-4.

These expensed expenditures constitute the remainder of business costs that are subtracted from sales revenues in arriving at the income-statement item "Net Profit Before Taxes." Thus, total business costs equal depreciation plus cost of goods sold plus expensed expenditures. However, because, by definition, expensed expenditures are costs which are identical with the productive expenditures constituting them, they can be added both to the sum of productive expenditures for the various fixed assets and for inventory and work in progress, and to the sum of depreciation plus cost of goods sold, without in any way affecting the difference between these magnitudes. It is a question of adding equals to unequals, which leaves the amount of the inequality unaffected. When added to the productive expenditures for the various fixed assets and for inventory/work in progress, they result in total productive expenditures constituting revenue or income to sellers. When added to depreciation plus cost of goods sold, they result in total business costs. Net investment is thus the difference between such productive spending and the business costs deducted from business sales revenues in computing profits, which is what I set out to prove.

The preceding discussion can be summarized in the form of the matrix shown as Table 15-2. In the table, productive expenditure, which equals the sum of $s_b + w_b$ and is represented by B , is broken down into $B_1 + B_2 + B_3$, where B_1 = productive expenditure on account of plant and equipment, B_2 = productive expenditure on account of inventory, and B_3 = productive expenditure that is expensed, i.e., written off as made. (For the sake of brevity, I have omitted reference both to "other fixed assets" in connection with plant and equipment and to "work in progress" in connection with inventory, and will hereafter continue this practice.) In exactly the same way, aggregate business costs d are broken down into d_1 , d_2 , and d_3 , where d_1 = depreciation cost, d_2 = cost of goods sold, and d_3 = cost constituted by productive expenditure that is expensed. In the table, I represents total net investment, while I_1 is net investment in plant and equipment, and I_2 is net investment in inventory.

Table 15-2 shows that when all costs together—namely, d —are subtracted from the totality of productive expenditure, B , the result is total net investment, I . It shows at the same time that when depreciation cost, d_1 , is subtracted from productive expenditure on account of plant and equipment, namely, B_1 , the result is net investment in plant and equipment, I_1 . At the same time, it

Table 15–2
Productive Expenditure Minus Costs Equals Net Investment

B	=	B ₁	+	B ₂	+	B ₃
– d	=	– d ₁	+	– d ₂	+	– d ₃
I	=	I ₁	+	I ₂	+	0

shows that when cost of goods sold, d_2 , is subtracted from productive expenditure on account of inventory, B_2 , the result is net investment in inventory, I_2 . Finally, the table shows that when costs constituted by productive expenditures that are expensed, d_3 , are subtracted from those same productive expenditures, B_3 , the result is zero, inasmuch as the two magnitudes are identical. Thus, the table shows simultaneously that net investment is productive expenditure minus costs and is equal to net investment in plant and equipment plus net investment in inventory, both of which in turn are equal to specific categories of productive expenditure minus specific categories of cost.

Table 15–2 makes it possible to relate the analysis I have presented, to contemporary national income accounting. We have seen that in contemporary national income accounting, net investment is defined as gross investment minus depreciation, and that gross investment itself is defined as gross plant and equipment expenditure plus the *net change* in inventories. The analysis I have presented can be understood in terms of a concept of gross investment that is larger than that which is usually called gross investment. Call it gross gross (double gross) investment. Gross gross investment is the entire expenditure that firms make for tangible goods obtained from other firms and for labor that they directly employ in the production of tangible goods. It is gross plant and equipment expenditure plus actual, gross expenditure for inventory—in terms of Table 15–2, it is $B_1 + B_2$. Subtract from this amount “cost of goods sold,” and one has what is usually called gross investment, for gross expenditure for inventory less cost of goods sold is the net inventory change. Net investment, obviously, is the difference between gross gross investment and depreciation plus cost of goods sold.

The addition of expensed productive expenditures to gross gross investment, of course, raises the latter to productive expenditure. Starting with productive expenditure, productive expenditure minus expensed expenditures equals gross gross investment expenditure. Gross gross investment expenditure minus cost of goods sold

equals gross investment. Gross investment minus depreciation equals net investment. All of this adds up to the fact that productive expenditure minus business costs equals net investment. At the same time, it helps to point the way to the integration of national income accounting with the wider, Aristotelian and classical-economics-based accounting framework of my own.

ii. Net Investment as the Tip of the Productive Expenditure Iceberg

Now that the relationship between net investment and productive expenditure has been made clear, it is possible to understand how contemporary national income accounting completely misinterprets the equality between national income and net national product. Table 15–3 provides an arithmetical example that clearly illustrates the illusion of viewing consumption spending as the main source of revenue and income payments in the economic system.

The table assumes the existence of a national income/net national product of 600 monetary units. This amount appears in the second row of the center column of the table, under the heading Y/NNP . The 600 is respectively equal both to a sum of 150 of profit income plus 450 of wage income, shown on the left-hand side of the table, and to a sum of 550 of consumption expenditure plus 50 of net investment, shown on the right-hand side of the table. Like the 600 of national income/net national product, these magnitudes are shown in the second row of the table, under the respective column headings for the various magnitudes, which occupy the first row of the table. (It should be observed that the table’s relative breakdown of national income between profit and wages, and of net national product between consumption expenditure and net investment, approximates the actual data found in a typical year.)

In the third row, the table states the profit and wage components of national income, and the consumption and net-investment components of net national product, in terms of their identical but differently ordered revenue-expenditure subcomponents. These revenue-expenditure subcomponents, of course, were explained earlier

Table 15–3
The Optical Illusion of Consumption as the Main Form of Spending

(1)	p	+	w	=	Y/NNP	=	C	+	I
(2)	150	+	450	=	600	=	550	+	50
(3)	$(s_c + s_b - d)$	+	$(w_c + w_b)$	=	Y	=	$(s_c + w_c)$	+	$(s_b + w_b - d)$
(4)	$(500+500-850)$	+	$(50+400)$	=	600	=	$(500+50)$	+	$(500+400-850)$

in this section, in my derivation of the equality between national income and net national product. I use the same algebraic notation in the table as I did in that derivation.

In the fourth row of the table, I supply specific quantitative values for each of the revenue-expenditure sub-components. Thus I assume that the 150 of profit income is the result of the existence of 1,000 of aggregate business sales revenues, less 850 of aggregate business costs. I further assume that the sales revenues are constituted by 500 of consumption expenditure, s_c , plus 500 of productive expenditure, s_b . I also assume that the 450 of wages are constituted by 50 of wages paid by consumers, w_c , plus 400 of wages paid by business firms, w_b . On the basis of previous discussion, I believe I am entitled to say that the assumed relative values of productive expenditure and consumption expenditure are in accordance with the actual facts.

It is obvious from the table that total expenditure and total revenue and income payments in the economic system are not the national income/net national product figure of 600, or even a gross national product figure of the 600 plus depreciation charges, but 1450. That is, it is the sum of product sales revenues of 1,000 plus 450 of wage payments. It is also obvious that the portion of total revenue and income payments constituted by consumption expenditure is a mere 550 out of this 1450 (i.e., $500s_c + 50w_c$), while the portion of total revenue and income payments constituted by productive expenditure is 900 (i.e., $500s_b + 400w_b$).

Indeed, things are virtually the *opposite* of what contemporary, Keynesian economics believes in connection with the relative quantitative significance of consumption expenditure. Instead of consumption expenditure constituting $1\frac{1}{2}$ ($550/600$) of aggregate spending and paying $1\frac{1}{2}$ of national income, while net investment constitutes and pays only $\frac{1}{2}$ ($50/600$), the truth is that

consumption expenditure constitutes only 550 out of 1450 of total spending and pays only a mere 50 of income out of 600 of income. By the same token, productive expenditure, concealed under the head of net investment, constitutes 900 out of 1450 of total spending, and pays 400 out of the 600 of national income. (Productive expenditure pays 400 out of the 450 of total wage income. The 150 of profit income is not literally “paid” by any expenditure. Five hundred of productive expenditure and 500 of consumption expenditure pay 1,000 of sales revenues, on which 150 of profit income is earned. Accordingly, one might attribute 75 of profit income to productive expenditure and 75 to consumption expenditure. This procedure would make productive expenditure responsible for 475 of national income, and consumption expenditure responsible for 125.)

What conceals the enormous role of productive expenditure in today’s national income accounts is that its presence is only implicit, in the form of net investment. Net investment, of course, is productive expenditure minus a magnitude that necessarily is always at least almost as large, namely, aggregate business costs. Thus, it is only a modest residual of productive expenditure that manages to come through in today’s accounts, thereby creating the impression that most spending and income payments take place in the form of consumption expenditure. This is why, insofar as sources of spending are concerned, I have described net investment as the tip of the productive expenditure iceberg.

Gross National Revenue

The preceding discussion shows that if one wants to make the national income accounts consistent with sound economic analysis and a proper recognition of the role of saving and productive expenditure in spending and income payments, a fundamental change in procedure is required. What I suggest is taking a new, much larger

Table 15-4
From Gross National Revenue to National Income and Net National Product

s	+	w	=	GNR	=	C	+	B
- d			=	- d	=			- d
p	+	w	=	Y/NNP	=	C	+	I

figure than gross national product as the conceptual starting point—namely, the sum of all revenue and income payments in the economic system. This total, *gross national revenue* (GNR), would consist of the sum of business sales revenues *s* plus wage incomes *w*, on the one side, and the sum of the consumption expenditure, *C*, plus the productive expenditure, *B*, that pays those revenues and incomes, on the other side. This is shown in the following equation:

$$s + w = GNR = C + B$$

Table 15-4 shows how it is possible to begin with this equation and then go directly to national income, on the left, and to net national product, on the right, by subtracting aggregate business costs *d*. On the left, *d* is subtracted from *s*, which results in aggregate profit *p*, and which reduces the sum of sales revenues plus wages, which is gross national revenue, to the sum of profits plus wages, which is national income. On the right, *d* is subtracted from productive expenditure, which results in net investment, *I*, and which reduces the sum of consumption expenditure plus productive expenditure (also equal to gross national revenue) to the sum of consumption expenditure plus net investment.

It should be noted that if, in this procedure, one subtracts all costs but depreciation cost, one arrives at the contemporary concept of GNP. That is, one has profit gross of depreciation on the left, and “gross” investment—i.e., plant and equipment spending plus the *net* investment in inventories—on the right. (One could, of course, introduce all of the intermediate steps described earlier in going from productive expenditure to net investment.)

More on the Critique of the Multiplier

The gross-national-revenue framework provides an excellent vehicle for illustrating in precise quantitative terms what is wrong with the Keynesian multiplier doctrine. That doctrine, it should be recalled, claims that a given increase in “investment” brings about a series of

further increases in consumption, thereby resulting in an increase in national income that is a multiple of the original increase in investment. For example, with a “marginal propensity to consume” (viz., fraction of additional income consumed at each round) of .75, 10 of additional net investment is supposed to result in 30 of additional consumption and thus 40 of additional national income.⁶¹

Now the gross-national-revenue framework necessary for the analysis of the multiplier has already been presented in Table 15-3, “The Optical Illusion of Consumption as the Main Form of Spending.” Table 15-3 is reproduced in Table 15-5, titled “The ‘Multiplier’ in the GNR Framework.” In Table 15-5 two new rows have been added to those of the earlier table. The first of these new rows, Row 3, shows the alleged operation of the multiplier in the superficial terms in which the Keynesians propound it, that is, in terms merely of net investment and consumption. Thus, in the rightmost column, the table shows net investment increased by 10, that is, to 60 from the 50 of the second row. One column to the left, it also shows consumption increased by 30, that is, from the 550 of the second row to the 580 of the third row. On this basis, in the center column, the table dutifully shows national income and net national product increased from 600 to 640. Unlike the Keynesians, however, Row 3 shows on its left-hand side that the 40 of additional net national product and national income takes place specifically in the form of 40 of additional *profit* income and no additional wage income. This is a result that the highly superficial analysis of the Keynesians is unaware of and incapable of realizing. For the ability to recognize it depends on the use of the gross-national-revenue framework, which appears in the next three rows of the table.

Of those next three rows, the first two, that is, Rows 4 and 5, are reproduced exactly from Table 15-3. Only the last, Row 6 in the table, is new. It shows, in the rightmost column, that 10 of additional net investment comes about by virtue of 10 of additional *s_b*, which rises

Table 15-5
The "Multiplier" in the GNR Framework

(1)	p	+	w	=	Y/NNP	=	C	+	I
(2)	150	+	450	=	600	=	550	+	50
(3)	190	+	450	=	640	=	580	+	60
(4)	$(s_c + s_b - d)$	+	$(w_c + w_b)$	=	Y	=	$(s_c + w_c)$	+	$(s_b + w_b - d)$
(5)	$(500+500-850)$	+	$(50+400)$	=	600	=	$(500+50)$	+	$(500+400-850)$
(6)	$(530+510-850)$	+	$(50+400)$	=	640	=	$(530+50)$	+	$(510+400-850)$

from 500 in Row 5 of the table to 510 in Row 6. In raising total productive expenditure by 10, in the face of an unchanged magnitude of aggregate business costs, it results in 10 more of net investment. To be precise, total productive expenditure is elevated from the sum of 500 of s_b plus 400 of w_b , namely 900, to 510 of s_b plus, once again, 400 of w_b , namely to 910. In the face of the same aggregate business costs, d , of 850, the result is a rise in net investment from 50 to 60.

At the same time, of course, inasmuch as s_b is not only a component of productive expenditure but also of business sales revenues, its new value of 510 must appear as sales revenues on the left-hand side of the Row 6. There its effect is to raise total sales revenues from 1,000, which is the sum of 500 of s_c plus 500 of s_b , to 1,010, which is the sum of 500 of s_c plus, this time, 510 of s_b . In the face of the same aggregate business costs, d , of 850, the result is a rise in aggregate profit from the 150 of Rows 2 and 5 to 160.

The rise in profits that is shown in Rows 3 and 6 is in fact much greater, namely, to 190 from 150. This is the result of the 30 of additional consumption spending that the multiplier doctrine alleges to occur on the basis of the 10 of additional net investment. The 30 of additional consumption spending constitutes 30 of additional business sales revenues, or at least something very close to 30 of additional business sales revenues. This is because the far greater part of private consumption spending is for goods and services of business firms, not for the labor of wage earners. For all practical purposes any additional demand for domestic servants can simply be disregarded.

Thus, on the right-hand side of Row 6, I show the rise in consumption as taking place entirely as a rise in s_c from 500 to 530, which has the effect of raising total

consumption from the sum of 500 of s_c plus 50 of w_c to 530 of s_c plus 50 of w_c , namely, from 550 to 580 of total consumption, C . At the same time, on the left-hand side of Row 6, the effect of the additional consumption is 30 more of business sales revenues and thus 30 more of aggregate profit. For business sales revenues are further increased from the sum of 500 of s_c plus 510 of s_b , to the sum of 530 of s_c plus 510 of s_b , that is, from 1,010 to 1,040. And because aggregate costs, d , remain at 850, the effect, as shown explicitly in Row 2 of the table, is to increase profits from 150 to 190.

It cannot be stressed too strongly that, consistent with the law of identity and the entire preceding discussion of this chapter, there is in this whole process absolutely no increase in the demand for labor by business or any further increase in the demand for capital goods subsequent to the initial 10 that gave rise to the increased net investment of 10. Furthermore, it should be realized that nothing essential is changed if we drop the assumption that all of the additional net investment is caused by a rise in s_b and assume instead that some of it results from additional w_b . If for example, 5 of the initial 10 of net investment had come about in this way, once again followed by 30 of additional consumption, the only effect would have been that the rise in profits, instead of being all 40 of the rise in national income, would have been 35, and the rise in wages, instead of being zero, would have been 5. (That is, the rise in wages would have been the wages that might have been contained in the one possible act of productive expenditure present.) Contrary to the multiplier doctrine, any rise in the demand for labor or capital goods depends—it must be said once again—on what is *not consumed, but saved and productively expended*.

4. Importance of Recognizing the Separate Demand for Capital Goods for the Theory of Capital Accumulation and the Theory of National Income

This chapter's stress on the fact that the demand for A is the demand for A and thus that the demand for capital goods and the demand for labor are separate and distinct from the demand for consumers' goods was the implicit basis of the theory of capital accumulation that I presented in Chapter 14.⁶² It was only by virtue of my having recognized the separate existence of the demand for capital goods, and the separate, distinct production of capital goods, that I was able to realize that capital goods are used to produce capital goods no less than consumers' goods. It was this, in turn, that led me to realize that once additional capital goods are brought into existence on the basis of a rise in saving, those additional capital goods themselves make possible a further increase in the supply of capital goods, through their contribution to the increase in production. It is impossible to make these connections if one believes that all that is produced are consumers' goods. In that case, one believes that additional capital goods are brought into existence exclusively by means of saving. This is because the additional capital goods brought into existence by saving are held to be a source only of additional consumers' goods. To have a further increase in the supply of capital goods, further saving is thought to be necessary.

Thus, the failure to recognize the separate existence of the demand for capital goods and the corresponding separate production of capital goods prevents the development of a sound theory of capital accumulation. However ironic, it leads both to an inadequate appreciation of the role of saving in capital accumulation and to a corresponding overemphasis on the role of saving in capital accumulation. It leads to a failure to see that fundamentally saving is to capital accumulation as force is to acceleration. That is, it leads to a failure to see that a given increase in saving and in the relative demand for capital goods can be the cause of continuing capital accumulation, while a further increase in saving and the relative demand for capital goods serves to bring about an acceleration in the rate of capital accumulation.⁶³ The failure to recognize the separate existence of the demand for capital goods and the corresponding separate production of capital goods also prevents recognition of the role of technological progress as a cause of capital accumulation in serving to maintain the productivity of the increasing supply of capital goods. In addition, of course, it prevents recognition of all other causes serving to increase production in general as thereby being sources of capital accumulation. In effect, if one does not heed the fact that capital goods as well as consumers' goods

are produced, one must be oblivious to almost everything that contributes to their supply.

My purpose here in recalling the theory of capital accumulation I presented in Chapter 14 is not only to show its implicit dependence on the recognition of the separate, distinct demand for capital goods and the separate, distinct production of capital goods. It is also to begin to show how when that analysis of capital accumulation is combined with the *explicit* recognition of separate, distinct demands for capital goods and labor as well as consumers' goods, it serves to provide a conceptual framework for the analysis of numerous other major questions in economics, including, above all, the determinants of aggregate profit and the average rate of profit in the economic system.

My analysis of the determinants of the rate of profit is reserved for the next chapter. Here, however, as a preliminary to that analysis, by means of providing further knowledge in connection with aggregate economic accounting and the determination of national income, I must ask the reader to consider Figures 15-5 and 15-6. These are elaborated versions of Figures 14-4 and 14-5, respectively, which were essential vehicles for conveying my analysis of the role of saving and the relative demand for capital goods in capital accumulation.⁶⁴ Figures 15-5 and 15-6 take the essential information supplied in Figures 14-4 and 14-5 concerning the role played by the relative demands for capital goods and consumers' goods in the context of an invariable money and show how those two figures respectively imply definite amounts of national income.

If we examine Figure 15-5, we see that in representing the demand for capital goods as 500 units of money and the demand for consumers' goods as a further 500 units of money, Figure 14-4 implies that *total sales revenues in the economic system are 1,000 units of money*. This is because total sales revenues in the economic system are nothing but the sum of the receipts from the sale of capital goods plus the receipts from the sale of consumers' goods, which, of course, as Figure 15-5 shows, are precisely equal to the expenditures made in buying capital goods and consumers' goods. (From the perspective of the buyers, every dollar of sales revenue is an expenditure that is made either for the purpose of making subsequent sales or not for the purpose of making subsequent sales. In the first case, it constitutes receipts from the sale of capital goods; in the second, receipts from the sale of consumers' goods.)⁶⁵ A total of 1,000 of such expenditures means a total of 1,000 of sales receipts.

Furthermore, under the assumptions on which Figure 14-4 was constructed, and which, of course, apply to Figure 15-5, it follows that the demand for capital goods of 500 in each year can be taken as a *cost* of producing

the output of the following year. This is because the capital goods in existence at the beginning of any year are all assumed to be used up or worn out in that very same year in the course of producing the supply of capital goods and consumers' goods available at the start of the following year. Thus, the 500 of outlays for capital goods in each year are a cost of producing the output of the next year because they are made for no other reason than for the purpose of producing that output and bringing in the sales revenues obtained in exchange for it. Figure 15-5 shows this total cost of 500 on account of capital goods as consisting of 250 of respective separate costs on account of capital goods, for the capital goods and the consumers' goods of the following year, each of which comes into being as the result of the use of 50 percent of the 500 worth of capital goods and of the labor of the year before.

In sum, Figure 15-5 shows 1,000 of sales revenues in the economic system in every year and 500 of costs on account of capital goods, which costs reflect the outlays to purchase capital goods in the year before. This is so at least starting with *Year 3*, which is the first year in Figure 15-5 that follows an explicit outlay of money to buy capital goods. Thus, in Figure 15-5, we can observe 1,000 of aggregate sales revenues in the economic system and at least 500 in aggregate costs in the economic system in every year from *Year 3* on.

As I have said, this difference between aggregate sales revenues and aggregate costs which are exclusively on account of capital goods, can be taken as representing national income. This follows from the fact that costs exclusively on account of capital goods exclude costs on account of wages.⁶⁶ Costs that exclude costs on account of wages are costs *minus* those wages. Thus, sales revenues minus costs that exclude wages are equal to profit *plus* those wages, which is to say, for all practical purposes, national income. In terms of a very simple equation,

$$\text{sales revenues} - (\text{costs} - \text{wages}) = \text{profits} + \text{wages} = \text{national income.}^{67}$$

The most important thing to keep in mind about national income is that it is necessarily the counterpart overwhelmingly just of consumer spending. We already know this from our derivation of the equality between national income and net national product, in the previous section of this chapter. It also follows from the fact that national income is sales revenues minus costs on account of capital goods. In Figure 15-5, of course, not only do costs on account of capital goods in any year equal the outlays for capital goods made the year before, but also the outlays remain the same from year to year—always being 500 units of money. As a result, in Figure 15-5,

sales revenues minus costs on account of capital goods also equals sales revenues minus the *current* demand for capital goods, since the current demand for capital goods is equal to the demand of the previous year and thus to the costs on account of capital goods deducted from sales revenues this year. Therefore, in Figure 15-5, national income equals only the remaining sales revenues, which represent the demand for consumers' goods alone. Indeed, in all circumstances, the national income earned in connection with the sales revenues of any year, can never exceed the consumer spending of that year by very much. The excess can be no more than the amount by which the current demand for capital goods exceeds the costs deducted from sales revenues on account of capital goods.⁶⁸

The Inverse Relationship Between National Income and Economic Progress in an Economy With an Invariable Money

The discussion of capital accumulation in Chapter 14, in particular the role of the demand for capital goods relative to the demand for consumers' goods, and now the realization that national income is the counterpart of consumption expenditure, imply that national income and economic progress can be *inversely related*. Economists have long known this to be the case in the context of inflation, in which national income rises merely as the result of rapid increases in the quantity of money and volume of spending, which at the same time undermine capital accumulation.⁶⁹ What the present analysis shows is that in the total absence of inflation, indeed, precisely in the context of an invariable money, in which the quantity of money and the aggregate demand for the products of business remain absolutely fixed, national income and economic progress are inversely related.

This conclusion becomes obvious when Figure 15-6 is observed. In Figure 15-6, the demand for capital goods is 600 units of money in each year from *Year 2* on, while the demand for consumers' goods has fallen to 400 units of money. We have already seen how this rise in the demand for capital goods and fall in the demand for consumers' goods brings about an acceleration in capital accumulation and economic progress from zero—the stationary economy of Figure 15-5—to 20 percent a year.⁷⁰ It is only necessary to observe now that *national income in Figure 15-6 falls to 400 monetary units from its previous height of 500 monetary units*. National income is only 400, and can only be 400, because total sales revenues in the economic system are still only 1,000—the sum of the demand for capital goods of 600 plus the demand for consumers' goods of 400—while costs on account of capital goods rise to 600. National income falls, because the rise in demand for capital goods increases the costs on account of capital goods which must

be subtracted from the unchanged total sales revenues. The amount by which sales revenues exceed the costs on account of capital goods, and thereby determine national income, is now only the diminished consumption expenditure of 400 units of money instead of the 500 units of money that it was in Figure 15-5. (As was the case in Figure 15-5, Figure 15-6 breaks down the total cost of capital goods into the separate portions chargeable to the respective production of capital goods and consumers' goods. Because 60 percent of the 600 worth of capital goods of each year from *Year 2* on are used up to produce capital goods for the next year, the cost of those capital goods, on account of capital goods, is calculated as 360. By the same token, the cost of the consumers' goods, representing the using of up of 40 percent of the 600 worth of capital goods of the year before is calculated as 240.)

The essential findings are shown on a year-by-year basis in Tables 15-6 and 15-7, which correspond to Figures 15-5 and 15-6 respectively. The only difference is that the tables extend the data of the figures out to *Year 5*. The tables show the demand for capital goods and the demand for consumers' goods in each year and the total sales revenues generated by the sum of these two demands. The generation of sales revenues is depicted graphically, by short lines drawn down from the respective demands for capital goods and consumers' goods in each year to a longer line drawn across and culminating in an arrow pointing up to the 1,000 of sales revenues in that year. Downward, rightward sloping arrows show the demand for capital goods in each year as determining the costs on account of capital goods which appear in the following year. National income in each year is shown as the difference between the 1,000 of sales revenues in each year and these costs on account of capital goods.

Thus, the conclusion is evident that, in the context of an invariable money, *national income and economic progress are inversely related*. Economic progress depends on the demand for capital goods, but the greater is that demand, the greater is the deduction of cost on account of capital goods from sales revenues, and thus the less that remains for national income, given aggregate sales revenues that are fixed.

This conclusion that the fall in national income is the accompaniment of more rapid economic progress must cause bewilderment to people who are accustomed to think of economic well-being and rising money income as inseparable. Thus, it is necessary to stress that the improvement in economic well-being is still fully present. It merely takes the form of *falling prices of products*. In an economic system with an invariable money—that is, once again, a fixed quantity of money and a fixed volume of aggregate spending to buy the products of business—a rise in the relative demand for capital goods and the growing supply both of capital goods and consumers' goods that it causes results in a continuing fall in the prices of capital goods and consumers' goods. Thus, from one year to the next, the diminished monetary amount of national income has a greater buying power.

If we compare Figures 15-5 and 15-6, we can observe that while national income in Figure 15-6 is only 400, in comparison with the 500 of Figure 15-5, the prices of capital goods and consumers' goods in Figure 15-6 fall every year, from *Year 3* on, in the ratio of 5: 6. This follows from the fact that, starting in *Year 3*, the same expenditures for capital goods and consumers' goods of 600 and 400 respectively, buy supplies of capital goods and consumers' goods that are twenty percent or six-fifths larger than the year before. Six-fifths the supplies,

Table 15-6
National Income in Figure 15-5

Year	Demand for Capital Goods	Demand for Consumers' Goods	Sales Revenues	Costs on Account of Capital Goods	National Income
1					
2	500	500	1,000		
3	500	500	1,000	500	500
4	500	500	1,000	500	500
5	500	500	1,000	500	500

divided into unchanged demands, result in prices that are five-sixths as great. In contrast, in Figure 15-5, where national income is 500 rather than 400, and the relative production of capital goods is correspondingly less, there is no increase in the supply of capital goods and consumers' goods, therefore no fall in the prices of capital goods or consumers' goods, and thus no increase in the buying power of incomes. In terms of *buying power*, the 400 of national income of Figure 15-6 further and further surpasses the 500 of national income of Figure 15-5.

Now it should certainly not be concluded from this discussion that there is no connection whatever between increasing production and rising money incomes. As I have pointed out several times before, there in fact is a connection. Under a system of commodity money, such as a gold or silver standard, a growing general ability to produce will almost certainly be reflected in improvements in the ability to extract and refine minerals, including gold and silver, the monetary commodities. Thus an increasing quantity of money and therefore a rising volume of spending and of money incomes will almost inevitably occur as *by-products* of the increasing ability to produce. The processes of rising money incomes and growing production will therefore be parallel to an important extent, at least under a system of commodity money. But even though parallel, the processes are nevertheless separate and distinct and must always be sharply distinguished in thought. As indicated in Chapter 12, in the discussion in which the concept of invariable money was introduced, just as a physicist or engineer conceives of the motion of objects as determined by a variety of distinct forces acting in combination and analyzes the effects of each one acting separately—for example, the combination of gravitation and air pressure,

or the combination of engine power, water current, and wind—so the economist must separately analyze the effects of changes in the relative demand for and production of capital goods and consumers' goods and the consequent changes in the rate of increase in the production and supply of goods for sale, on the one side, and changes in the quantity of money and volume of spending to buy those goods, on the other. Having done this in analyzing the process of capital accumulation under the assumption of an invariable money, we are able to recognize that, with any given quantity of money and volume of spending for the goods and services of business, the rate of capital accumulation and economic progress is in fact inversely related to the height of national income.

Overthrow of the Keynesian Doctrines of the Balanced-Budget Multiplier and the Conservatives' Dilemma

It should be realized that the recognition of the inverse relationship between nominal national income and economic progress in the context of an invariable money constitutes a substantive overthrow of the Keynesian doctrine of the "balanced-budget multiplier." That doctrine, which is propounded in almost every contemporary "macroeconomics" textbook, claims that an equal increase in taxes and government spending raises the national income by an equivalent amount—that, for example, if both taxes and government spending are increased by \$10 billion, national income will also increase by \$10 billion. The Keynesians, of course, assume that such an increase in national income is all to the good, and is on the order of a lesser miracle achieved by government intervention.⁷¹

Table 15-7
National Income in Figure 15-6

Year	Demand for Capital Goods	Demand for Consumers' Goods	Sales Revenues	Costs on Account of Capital Goods	National Income
1					
2	600	400	1,000		
3	600	400	1,000	600	400
4	600	400	1,000	600	400
5	600	400	1,000	600	400

What the Keynesians have failed to see in their zeal to overturn common sense is that under the operation of the “balanced-budget multiplier,” national income rises by virtue of a form of consumption—viz., government spending—taking the place of demand for capital goods. To finance the additional government spending, the taxpayers must reduce their saving and expenditure for capital goods. If the fall in expenditure for capital goods finances the whole of the rise in government spending, then, indeed, national income will increase by an equivalent amount. This is because aggregate sales revenues in the economic system will remain the same—with receipts from the sale of consumers’ goods to the government or its clients taking the place of receipts from the sale of capital goods to business—while the costs deducted from sales revenues on account of capital goods will fall. But this result, of course, is accompanied by a corresponding decline in the relative production of capital goods and therefore in economic progress and prosperity. Thus the Keynesians totally misinterpret the significance of the rise in national income that would materialize. What the Keynesians have done here is failed to heed the distinction advanced by Ricardo between “value,” which can be understood as money national income in the context of an invariable money, and “riches,” i.e., real physical wealth. As I have pointed out more than once, and as Ricardo pointed out in the early nineteenth century, the two are separate and distinct and can move in opposite directions.

The recognition of the inverse relationship between nominal national income and economic progress is also a refutation of the alleged conservatives’ dilemma that is founded on the balanced-budget multiplier doctrine. The “conservatives’ dilemma” is the alleged dilemma of having to choose between stimulating the economic system either by means of budget deficits, if one relies on the standard government-spending or tax multipliers propounded by the Keynesians, or by means of an increase in the size of government spending several times greater than what would supposedly be required in connection with a deficit. Thus, for example, it is claimed that with a government-spending multiplier of 4 and a tax multiplier of -3 (both of which allegedly follow from the same “marginal propensity to consume”), national income could be increased by a given amount, such as \$10 billion, in either of three ways: by increasing both taxes and government spending by \$10 billion and thus maintaining a balanced budget, or by incurring a budget deficit of \$2.5

billion brought about through increased government spending with no accompanying increase in taxes or, finally, by incurring a budget deficit of \$3.33 billion brought about by tax reduction with no accompanying decrease in government spending. The alleged dilemma represented by such an example is that economic prosperity requires that American conservatives choose between their two cherished principles of balanced budgets and small government. Allegedly, they must accept either deficits with relatively small government or, if they insist on maintaining balanced budgets, much greater growth in government, because one or the other is supposedly necessary for a given increase in national income.⁷²

What my analysis has shown, both in this section and in my critiques of the multiplier doctrine earlier in this chapter, is that any increase in national income brought about in such ways is inversely related to capital accumulation and economic progress, because it would represent a rise in the relative demand for and production of consumers’ goods at the expense of the relative demand for and production of capital goods. It would also represent a fall in the share of consumption based on wage payments, which, like the demand for capital goods, depends on saving and productive expenditure. National income is simply not the standard of economic prosperity. Any rise in national income accomplished by means of the demand for consumers’ goods rising at the expense of the demand for capital goods is the same in its nature as moving from the conditions of Figure 15–6, with its national income of 400 and rapid capital accumulation and economic progress, to the conditions of Figure 15–5, with its national income of 500 and economic stagnation. Thus, American conservatives can continue to cherish both small government and balanced budgets, secure in the knowledge that both are essential requirements of economic progress and prosperity, even if in the conditions of a given quantity of money and volume of spending, they mean a smaller national income—indeed, precisely because they mean a smaller national income in such conditions.⁷³

Thus, this chapter has conclusively demonstrated in every way the overwhelming role of saving and productive expenditure in the generation of aggregate demand. In the process, it has rid the science of economics of significant elements of seeming paradox and given good indication of the importance of sound ideas concerning saving and spending for the rest of economic theory.

11. *Ibid.*, p. 109.
12. Gardner Ackley, *Macroeconomic Theory* (New York: The Macmillan Company, 1961), p. 28. To his credit, Ackley is aware that “Final products might be limited to consumer goods and goods sold to the government (collective consumption).” (*Ibid.*) He is aware that the actual contemporary practice of including the production of plant and equipment in GNP represents a contradiction of the final products approach. He writes: “There is much to be said for the idea that new capital goods are not final products. They are certainly not wanted for their own sake, but only to produce (directly or indirectly) other final products. The machine services which contribute to the production of bread are essentially like the flour. Machine methods are more productive than hand methods; therefore machinery is produced and used. But sooner or later this production of machines means that more bread will be produced than otherwise. Having counted the production of bread, this argument would have it that we should not also count the production of machinery.” (*Ibid.*, p. 29.)

19. These considerations, and the rest of this subsection, imply, of course, that the so-called accelerator doctrine of the Keynesians is completely mistaken. For the accelerator doctrine explains increases in the aggregate demand for capital goods on the basis of increases in the aggregate demand for consumers’ goods. For further discussion of this error, see below, n. 22 of this chapter.
20. See above, pp. 475–480.
21. See above, pp. 140–141.
22. Perhaps the best that can be said for the proponents of the idea that increases in the aggregate demand for consumers’ goods are the cause of increases in the aggregate demand for factors of production is that they confuse the effects of increases in the aggregate demand for consumers’ goods with the effects of increases in the quantity of money or decreases in the demand for money for holding. Under such conditions, in which aggregate monetary demand increases, an increase in the demand for consumers’ goods is probably accompanied by an increase in the demand for factors of production. But it would have been accompanied by a greater increase in the demand for factors of production if the increase in consumption were smaller. In that case saving, the indispensable precondition of the demand for factors of production, would have been greater and thus so too would have been the demand for factors of production.
23. The precise nature of this relationship will become clearer in the elaboration of the theory of profit and the role played by an excess of consumption expenditure over wage payments in determining an excess of demand for products over demand for factors of production and thus of sales revenues over costs. See below, pp. 725–736. See also below, pp. 689–690.
24. See above, p. 301 and pp. 650–653. See also pp. 653–655.
25. See again above, pp. 653–655.
26. This fact is clearly recognized in the theory of profit and interest propounded by von Mises under the name the theory of originary interest. Cf. von Mises, *Human Action*, 3d ed. rev. (Chicago: Henry Regnery Co., 1966), pp. 526–527.
27. See, for example, the extensive quotation from Samuelson and Nordhaus, a few paragraphs below in the text.
28. Samuelson and Nordhaus, pp. 167–168.
29. For elaboration of this point, see below, pp. 707–708.
30. See below, pp. 702–705, for a discussion of the nature of

net investment.

31. On these points, see above, pp. 622–629 and 631–634.
32. See, for example, Samuelson and Nordhaus, p. 168.
33. Cf. *ibid.*, pp. 153 and 181, where investment is described as “autonomous”—viz., emanating from outside the system.
34. For examples of these errors, see again Samuelson and Nordhaus, pp. 176–183.
35. See above, pp. 573–573.
36. On the nature of consumption and capital, see above, pp. 444–447.
37. Cf. U.S. Department of Commerce, Office of Business Economics, *National Income*, 1954 ed. (Washington, D. C.: U.S. Government Printing Office, 1954), p. 164.
38. On the harmful effects of government interference with the fall in wages and prices in a depression, see above, pp. 580–594. On the deflationary potential of fractional reserve banking, see above, pp. 513–514.
39. A further significant point that deserves mention in connection with “hoarding” is that it operates to speed the adjustment process of the fall in wages and prices that is necessary to restore full employment. This is because in reducing spending, it increases the pressure on wage rates and prices to fall. See Murray N. Rothbard, *Man, Economy, and State*, 2 vols. (Princeton, N. J.: D. Van Nostrand Company, Inc., 1962), 2:691–692.
40. See below, pp. 954–963.
41. As I have already shown, revenue and income that is saved is also typically spent *faster* than revenue and income that is consumed. On this point, see above, p. 518.
42. The employment statistics can be found in *The Federal Reserve Bulletin*, September, 1993, p. A45.
43. For elaboration of this point, see below, pp. 843–847.
44. See below, pp. 778–787.
45. Such government expenditures, of course, are fully consistent with the principle that business is the source of its own demand. This is because the taxes that finance them are always paid either directly by business enterprises themselves, by wage earners and dividend and interest recipients with funds received from business enterprises, or by people who receive funds from the members of these groups, such as domestic servants.
46. On this subject, see below, pp. 739–741. To an important but lesser extent, taxes on wages also reduce the demand for capital goods and labor. They reduce it insofar as their effect is to reduce the savings of wage earners, who then either cannot finance productive expenditure to the same extent or are led to borrow savings in competition with business, in order to finance their purchase of expensive consumers’ goods, such as housing and automobiles.
47. For a full account of these effects, see below, pp. 922–950.
48. J. S. Mill, *Essays on Some Unsettled Questions of Political Economy* (1844; reprint ed., New York: Augustus M. Kelley, 1968) pp. 48–49. To be fully accurate, one need only add to Mill’s position recognition of the fact that production and employment can be held far below their potential limit at any given time by government interference in the monetary system and the consequent boom-bust pattern of business activity, and that such damage can be indefinitely protracted by further government interference in the form of maintaining artificially high wage rates and prices in the contraction phase. See above, pp. 580–594 and 938–942.

49. See above, pp. 559–580.
50. On the role of saving in capital accumulation and a rising productivity of labor, see above, pp. 622–629 and 631–632. See also below, p. 824.
51. For the discussion of natural resources, see above, pp. 63–66.
52. See above, pp. 622–629, especially Figures 14–4 and 14–5 and the surrounding discussion.
53. On this last point, see above, pp. 531–533.
54. See, for example, Samuelson and Nordhaus, pp. 110–116.
55. See below, p. 705.
56. See, for example, Samuelson and Nordhaus, p. 165, Figure 8–10, which is titled “HOW CONSUMPTION AND INVESTMENT DETERMINE OUTPUT.”
57. Concerning my treatment of interest, see below, pp. 720–721. Previous discussion, on pp. 456–459, has made it clear that most of what is described as net rental income of persons in today’s national income accounts is purely fictional in nature. It should be obvious in the light of that discussion that any actual net rental income, whether in letting rooms or apartments, houses, automobiles, computers, or whatever, is profit.
58. See above, pp. 444–447.
59. The use of lower-case s_c to represent sales revenues paid by consumers should not be confused with the previous use of upper-case S_C to represent the supply of consumers’ goods produced and sold, especially since the former is actually interchangeable with the *demand* for consumers’ goods, D_C . Also, I use the subscript b rather than p , to avoid confusion with aggregate profit, which is represented by p . One can think of b as standing for *business* expenditure, which, of course, is synonymous with productive expenditure.
60. It should be realized that while productive expenditure is an expenditure, net investment is not. As the difference between productive expenditure and business costs, its actual nature is that of an accounting abstraction, not an expenditure.
61. See above, pp. 690–691, in particular the quotation from Samuelson and Nordhaus.
62. See above, pp. 622–642.
63. This is the case in the context of an invariable money and its fixed aggregate demand for the products of business, which is the essential analytical framework for establishing causal relations in economics. In such conditions an increase in saving and the demand for capital goods is both an absolute increase and a relative increase at the same time.
64. See above, pp. 624 and 625.
65. See above, pp. 444–447.
66. They also exclude costs on account of interest. However, our practice, it should be recalled, is to count interest and “net rental income of persons,” which are the two remaining components of national income, as part of profits. See above, this page, n. 57. Because it is not germane to the present analysis, we also omit from consideration incomes generated in the so-called consumer and government sectors, notably the demand for consumers’ labor.
67. The fact that sales revenues minus costs on account of capital goods equals profits plus wages was previously demonstrated in connection with the exposition of the Marxian exploitation theory. See above, pp. 605–607.
68. I must point out that the national income earned in connection with the sales revenues of a given year includes an import-

ant component that was earned in previous years, and that an important component of the national income earned in the current year is earned in connection with sales revenues to be brought in, in future years. For example, part of the national income earned in connection with this year's sales revenues represents wages paid in the previous year (or earlier years) to workers who helped to produce items held in this year's opening inventories. It also includes significant amounts of wages paid as far back as previous decades and generations to workers who helped to build plant and equipment in existence at the beginning of the current year. By the same token, part of the wages paid this year are credited to inventory and plant and equipment accounts and will be chargeable against sales revenues only next year and, to be sure, in future decades and generations. As a result, it does not follow that national income in any given year exceeds the consumption expenditure of that particular year exclusively by the excess of the current demand for capital goods over the costs deducted from sales revenues on account of capital goods.

69. For a discussion of the destructive effects of inflation on

capital accumulation, see below, pp. 930–938.

70. See above, pp. 622–629, especially Figures 14–4 and 14–5 and the surrounding discussion. There the reader will see the basis of the derivation of the specific outputs of capital goods and consumers' goods in each year of Figure 15–6.

71. See, for example, Samuelson and Nordhaus, *Economics*, 13th ed., pp. 181–182; Willis L. Peterson, *Principles of Economics Macro*, 6th ed. (Homewood, Ill.: Richard D. Irwin, Inc., 1986), pp. 235–236; Gordon Philpot, *The National Economy, An Introduction to Macroeconomics* (New York: John Wiley & Sons, 1980), p. 81. The balanced-budget-multiplier doctrine was originated by Trygve Haavelmo, and presented for the first time in his article, "The Multiplier Effects of a Balanced Budget," *Econometrica*, October 1945.

72. See Philpot, *National Economy*, p. 81.

73. It should be realized that national income and economic prosperity are also inversely related in the case in which a rise in national income is brought about by means of an increase in the taxation of wage earners and use of the proceeds to raise the demand for labor. See above, pp. 648–650.

CHAPTER 16

THE NET-CONSUMPTION/NET-INVESTMENT THEORY OF PROFIT AND INTEREST

PART A

THE POSITIVE THEORY

1. The Nature and Problem of Aggregate Profit

In Chapter 13, I showed how production and supply are the source of demand in the sense of purchasing power—that is, real demand. In Chapter 15, I showed how saving and productive expenditure are the source of the great bulk of spending in the economic system. This conclusion followed from the fact that they not only make possible the demand for capital goods, which in a modern economic system almost certainly surpasses the demand for consumers' goods, but also the payment of wages by business, out of which comes the great bulk of consumer spending.¹ In this chapter, I will make good on the promise I made in Chapter 15 to show how business—taken in the aggregate—is the source not only of the monetary demand for its own products, but of a *profitable* monetary demand for its products. As I promised, I will show how business “itself generates a monetary demand that is fully sufficient for the profitable sale of its products . . . in the mere fact of purchasing capital goods and paying wages and in declaring dividends and paying interest” and how “in addition, the very increase in production itself operates to add further to both the real and the nominal rate of profit.” I will show, indeed, how there are “virtual *springs* to the restoration of profitabil-

ity” waiting to be unleashed whenever inflation and credit expansion bring on a financial contraction and deflation and thereby temporarily impair business profitability or wipe it out altogether.²

In this chapter, I will explain the determinants both of the aggregate amount of profit in the economic system and of the average rate of profit in the economic system. I will present a theory of profit which will show that in a society characterized by consistent laissez-faire capitalism, and thus free of financial contraction brought on by a preceding inflation or credit expansion, the average rate of profit is always determined at a point that is both high enough to make investment worthwhile and, at the same time, as low as the security of property and all rational provision for the future make possible. Thus, I will show—in contrast to the claims of the Keynesians and the Marxists—that the rate of profit is neither “too low” nor “too high” and that neither pretext constitutes grounds for a policy of government intervention or socialism.³

The theory of profit I will present in this chapter is the basis on which I was led to the development both of much of the material that I have already presented, in previous chapters, and of much of the material that is yet to come, in subsequent chapters. It is the basis of my having arrived at virtually the whole of the analysis I presented in Chapter 11 and in Chapters 13–15, from the definition of productive expenditure and consumption expenditure through the critique of the conceptual framework of the exploitation theory, the exposition of the philosophy of

productionism, Say's Law, the causes and cure of mass unemployment, the productivity theory of wages, and the development of my system of aggregate economic accounting. The only major doctrine presented in those chapters concerning which I cannot fully claim my theory of profit to be the basis of my exposition, is the doctrine that the demand for *A* is the demand for *A*. This is because it was my reading of John Stuart Mill's statement of this doctrine, in the form "demand for commodities is not demand for labour," that precipitated my development of my theory of profit. My theory of profit, as I will show, rests substantially on recognition of the truth grasped by Mill in his famous proposition. Of course, in turn, my theory of profit greatly reinforces and amplifies the truth of that proposition.

In this and subsequent chapters, my theory of profit will provide both the basis of analysis of questions I have not yet considered in this book and a wider perspective and more comprehensive theoretical framework for the analysis of questions that I have already considered. It will thereby make possible both the acquisition of important new knowledge, and valuable reinforcement, amplification, and integration of knowledge that the reader has hopefully already acquired to an important degree.

Before turning to the presentation of my theory of profit, however, it is necessary to attend to a number of important preliminary matters, starting with my treatment of interest.

The Treatment of Interest

The theory of profit I will expound will explain not only the average rate of profit in the economic system but also the rate of interest. The explanation of the rate of interest will follow from the explanation of the rate of profit.

In explaining the rate of profit, my purpose will be to explain what makes possible an excess of business sales revenues over business costs that are exclusive of interest. In other words, I will continue my practice of taking profits as gross of interest cost, that is, prededuction of interest cost. The average rate of profit that I will explain will be the amount of profit thus understood, divided by the amount of capital invested in the economic system both by equity investors—i.e., stockholders, partners, and sole proprietors—on the one side, and by bondholders and other creditors, on the other. In other words, it will be the rate of return found by dividing the sum of profit income earned by business firms plus interest paid by business firms, by the sum of all capital invested in business firms. The result will approximate what many would call the average rate of return on capital invested.⁴

As I have already shown, the rate of profit taken

prededuction of interest determines the rate of interest that business borrowers are able and willing to pay. In order for them to borrow, they must expect to earn a rate of profit in this sense that is greater than the rate of interest they are asked to pay. At the same time, of course, insofar as business firms are sources of loanable funds, the rate of interest they ask as lenders depends on the rate of profit they expect to be able to make by investing the funds in question in their own operations. In these ways, the rate of profit determines the rate of interest.⁵

In addition to being the determinant of the rate of interest, it is the rate of profit inclusive of interest that must be analyzed in order to deal with all the leading questions of economic theory that pertain to the rate of profit and interest taken together, such as the effect on the rate of profit and interest of capital accumulation and of falling prices caused by increased production. It is also this rate of profit that must be analyzed in order to deal with the doctrines of Marxism and Keynesianism, which are directed at the determination and the significance precisely of this rate of profit.

As a result of these considerations, interest payments will enter into the present analysis only in the same way as do dividend payments and the draw of funds by partners and sole proprietors, that is, neither as a productive expenditure nor as a business cost, but only as a source of demand for consumers' goods by businessmen and capitalists.

The existence of financial institutions, such as banks and insurance companies, may appear to introduce an important complication into the treatment of interest payments, namely, the fact that a substantial portion of interest payments has acquired the status of business sales revenues, from which various costs are deducted and on which profit is earned. Among the costs deducted, of course, are typically further interest payments. For the sake of ease of analysis, I shall simply ignore the existence of this phenomenon and assume that all interest paid by business firms is paid to individuals, to whom it constitutes equivalent net income.
